We record with regret the death, on April 10, of Mr. J. W. Leitch, the founder and head of John W. Leitch and Co., Ltd., Milnsbridge Chemical Works, Huddersfield.

The death is announced of Mr. John H. Yocum, president of Yocum Faust, Ltd., London, Ontario, a well-known leather chemist who joined this Society in 1894.

Prof. A. W. Reinold, formerly professor of physics in the Royal Naval College, Greenwich, died on April 11, at the age of 77 years.

The death is announced of Dr. P. Jannasch, formerly honorary ordinary professor of chemistry in the University of Heidelberg, aged 79.

PARLIAMENTARY NEWS.

HOUSE OF COMMONS.

Farina Mills.

In reply to questions put by Mr. J. Gardiner concerning a company formed to erect mills in this country for the production of farina, Sir P. Lloyd Greame said that the company was promoted by private individuals with Government support. The capital invested by the promoters was £20,000, and the cost of the four mills acquired at King's Lynn, Boston, Monikie, and Hull was £247,000. The King's Lynn and Boston mills had produced 1875 and 150 tons of farina respectively, but the Boston mill had been sold, and the other mills were on sale. Private subscribers were paid out at par.—(Apr. 11.)

British Dyestuffs Corporation, Ltd.

Sir P. Lloyd Greame, in reply to an inquiry by Mr. Hogge concerning the appointment of three new directors to the board of the above Corporation, stated that the appointment of directors (other than Government directors) to the board did not require the consent of the Government, as the latter had no controlling interest in the Corporation.—(Apr. 11.)

Chemical Warfare Committee.

Mr. Rawlinson asked the Chancellor of the Exchequer whether his attention had been called to the hardship caused to the members of the Chemical Warfare Committee by the Treasury rule that to obtain remuneration they must prove actual pecuniary loss due to their service on the Committee; and whether, as some of the members received fixed incomes or were engaged in research work, he would arrange that members entitled to remuneration should not be compelled to show actual loss.

Lieut.-Com. Young, in a written reply, said that members of commissions and committees were usually willing to serve their country without specific remuneration in cases where such service did not entail actual loss, and he saw no reason to depart from the usual rule in this particular case. —(Apr. 12.)

Basic Slag.

Sir A. Boscawen informed Sir J. Norton-Griffiths that the prices of basic slag, 84 shillings per ton from January to May, 1920, and now 127s. 6d. per ton, were maximum prices which the manufacturers, by agreement with the Ministry, undertook not to exceed. The higher price was sanctioned in view of the increased cost of transport and production, and because without such an agreement the price would probably have gone still higher. The agreement expired on May 31, 1921, and would not be renewed. Export of basic slag was prohibited, save under licence, as the supply of the higher grades was insufficient to meet home demands. The Government had never owned any basic slag other than the small quantities required for use in the Ministry's farm settlements or experiments. No licence was required for the importation of basic slag, and during the six months ending March 31, 1921, 15,769 tons, worth £125,832, had been imported, the bulk of which was probably unground.— (Apr. 13, 20.)

Coal Industry (Capital, Profits, and Wages.)

Mr. Bridgeman, answering Mr. Hurd, said that, exclusive of coke ovens and by-product plant, the total capital employed in the coal-mining industry was approximately £180,000,000, not including new money invested in the industry during 1920. The percentage of profits earned, before deducting profits carried to reserve and capitalised, was estimated as follows:—Average of five years ended March 31, 1914, 9·8 per cent.; average 1915—1917, 17·0 per cent.; average 1918—1921, 15·5 per cent. During the seven years ended March 31, 1921, it was estimated that £40,000,000 was appropriated from profits to capital, leaving available for dividends, partners' drawings, and income-tax, a sum representing a possible yield of 11¾ per cent. on the average capital employed. The total amounts of wages paid were £91,000,000 in 1913 and £261,721,000 in 1920; the profits in these two years were £21,000,000 and £27,000,000, respectively.—(Apr. 19, 22.)

REPORTS.

General Report on the Economic Situation of Denmark at the Close of 1920. *By* R. M. Turner, *Commercial Secretary to H.M. Legation, Copenhagen. Pp.* 54. (*London: H.M. Stationery Office.* 1921.) *Price* 1s. 3*d. net.*

The present unfortunate economic situation in Denmark is to a large extent due to the high prices that have to be paid for imported fuel, which is now obtained mainly from the United States. It is therefore not surprising that increasing interest is being taken in the development of home resources, in water-power schemes, electricity, and the extensive deposits of peat. A marked feature of the past year has been the depreciation of the Danish krone, which has been investigated by a Government commission but so far without result, although it may soon lead to a revision of the tariff system. Unemployment and the cost of living have both steadily increased, and the curtailment of credits by the banks has affected trade and industry.

The condition of agriculture, the main source of wealth, is favourable. Sugar-beet was cultivated over about 95,300 acres, or some 6400 acres less than in 1919, when the production was 135,000 metric tons; about 10,000 t. of the 1919 crop was exported. Experiments on the production of sugar-beet seed have so far not led to any tangible result, but the seed industry in general has been developed, and more potatoes have been cultivated and exported. The oil-crushing and margarine industries have been active, and it is noteworthy that the importation of edible oils has diminished, and that of oil-bearing nuts and seeds has increased. The fact that it is advantageous to export butter in order to improve the exchange augurs well for the prospects of these industries. Of margarine some 45,000 t. was produced during 1920, which is about 75 per cent. of the output capacity; and nearly all of it was consumed in the country, regulations as to packing, colouring, etc. effectually preventing exportation. Much of the raw material for the leather industry is obtained in the country; imports of heavy hides and tanning extracts and exports have decreased, but on the whole the industry, which is practically controlled by a single group, has been well employed. Shortage of fuel has seriously affected cement and brick manufacture, and the textile industry has been passing through a bad time owing to shortage of imported raw materials, fuel, and foreign competition. These causes, together with increased labour costs, have also affected the metal industry, which on the whole has been fairly well occupied, and the chemical industry, which, in addition, has had to contend with German competition. The manufacture of fertilisers has continued favourably notwithstanding importation of foreign superphosphate, etc., which depressed prices. During the first nine

months of 1920, 82,095 t. of raw phosphate was imported, compared with 35,698 t. for the whole of 1919, and the corresponding figures for superphosphate are 45,565 t. and 66,864 t., respectively. In the same period there was imported 42,234 t. of Chilean and Norwegian saltpetre, representing a decrease of 21,098 t. over the corresponding nine months of 1919, but the imports of the Norwegian fertiliser, 32,819 t., increased by 10,492 t. The importation of potash fertilisers decreased from 92,142 t. to 3126 t. for the nine-month period. Imports of glass and glassware, and of porcelain and faience (mainly from Germany) declined notably; and of metals there were imported increased quantities of cast iron (28,600 t.), black plates (44,000 t.), tinplate (6700 t.), and raw lead (3700 t.).

The main facts in the economic position to be noted by U.K. manufacturers are, apart from the question of exchange, the existence of large stocks in the country and foreign, especially German, competition.

Rapport sur le Commerce et l'Industrie de la Suisse. 1919. *Pages* 495. *Publié par le Vorort de l'Union suisse du Commerce et de l'Industrie.* 1920.

The year 1919 was a chequered one for the Swiss heavy chemical industry. Liquidation of war stocks and widely fluctuating prices combined to make markets unstable, and until stocks had been disposed of towards the middle of the year and the textile industry had resumed activity, production was not always able to meet demand. The shortened working day also restricted production.

The foregoing applied chiefly to sulphuric acid, but oleum was always in demand. Pyrites was in sufficient supply, but the price went up instead of down. Switzerland was fortunate in not having embarked on the manufacture of sulphuric acid from calcium sulphate, as this process has not fulfilled expectations. Lack of coal and sulphuric acid prevented over half the hydrochloric acid and sodium sulphate plants from working, in spite of the brisk demand; imported rock salt was used and hydrochloric acid was imported at prices below the production cost in Switzerland. The manufacture of nitric acid from atmospheric nitrogen by the arc process, which was actively pursued during the war, fell off, and as many consumers imported saltpetre or nitric acid from abroad, the factories diverted production to sodium and calcium nitrates. The soda industry, which suspended work at the end of 1918, recommenced on a small scale in June, 1919, and by the end of the year was able to meet requirements. In the fertiliser industry supplies of phosphates were no easier to obtain than during the war, and prices remained high; but little basic slag was imported, although potash salts were in plentiful supply. The electrochemical and electrometallurgical industries suffered under the prevailing economic depression, and many of the works had to strike out along new lines. Owing to the termination of war contracts only 2 or 3 of the calcium carbide factories that were running in 1918 continued to work. The following quantities of carbide were exported in the years 1913—1919 (in metric tons):—31,790, 35,950, 55,410, 58,010, 59,450, 75,840 and 36,890 t.

The manufacture of cyanamide was affected by a smaller demand and foreign competition, the output being reduced from 40,000 t. in 1918 to 9000—10,000 t. in 1919. Little improvement could be foreseen for the aluminium industry, which has suffered from the development of the industry in England, the United States, and Scandinavia. The production and export of ferro-alloys were very small. Some progress was made in the electric-smelting of iron scrap, and the output was estimated at 16,000 tons; smelting direct from the ore would only be commercially feasible in Switzerland were electric current available at about 1 centime per kw., and this is not possible. The export trade in chlorates and perchlorates was extremely small, and the manufacture of perchlorates had to be discontinued. The market for caustic soda, chloride of lime, chlorine, and similar products was fairly good, and the manufacture of sodium, although not for export, was continued at the Monthey works of the Swiss Society of Chemical Industry, where it is used in the manufacture of synthetic indigo. The country's requirements in chlorine are covered by the output of the Monthey works, and the production of this gas has apparently become stationary. Manufacture of perborate was abandoned, as the current consumption was too great, but the output of other minor products, such as hydrogen peroxide and persulphate, improved. Electrolytic oxidation and reduction are used in the Swiss dyeworks, but details are not available.

From the middle of 1919 the demand for coal-tar dyes has been so great that the factories have not been able to meet it; the production could be increased many times were sufficient raw materials, especially coal, available. Exportation of dyewares to France in 1919 was very severely handicapped by the French official regulations and duties. No difficulty was experienced in exporting to England, where the Trade Licensing Sub-committee granted import licences freely. All the dye-works manufactured a wider range of colours, although not to the same extent as before the war. Production of synthetic indigo was restricted by the shortage of aniline oil; nevertheless, both production and sales were about twice as large as in 1918. Mainly owing to excessively high prices, to a great extent adventitious, the export trade in synthetic perfumes was very much better than in 1918, but, in spite of this, the outlook for the industry was held to be very doubtful. The mineral colour and varnish industry experienced a bad year as it was congested with stocks purchased at war-time prices and could not dispose of them. The manufacture of explosives was necessarily curtailed, and the future of this industry was not regarded cheerfully except in so far as the development of water-power resources would call for considerable supplies

Of the many difficulties which confronted the manufacture of pharmaceutical chemicals, the reduction in the length of the working day was the greatest and had the most effect in raising production costs; in the latter part of the year firms which did not also manufacture dyes were scarcely able to make ends meet. Exportation was small and very difficult owing to collapsed exchanges; and the fairly satisfactory results which were obtained were due to the absence of foreign competition. According to one authority, the year 1919 was worse than any of the years of the war. The soap industry also recorded an unfavourable year. Large quantities of raw materials purchased at high prices during the war were delivered to the last kilogram, and at the same time buyers stood aloof waiting for prices to fall, and foreign wares, particularly Spanish, were thrust upon the market. The slump in the building trade naturally affected the cement industry which, in spite of lower prices, worked at only half-capacity. Manufacturers of porcelain and faience had to contend with importation from Germany and Lorraine, but makers of common pottery were in a better position, as their raw materials are found in the country. Glass manufacture was badly hit by the shortage of fuel; before the war the cost of fuel was 15—25 per cent. of that of the finished product, now it is about 60 per cent. The three glass-bottle factories produced regularly, and a small proportion of the output was exported.

Other subjects included in this comprehensive report are textiles, metals, engineering, preserved foodstuffs, leather, rubber, etc., together with much statistical information.

GOVERNMENT ORDERS AND NOTICES.

Former Enemy Aliens and the Dyestuff Industry.—The Board of Trade announces that by notice published in the *London Gazette* of April 8, the provisions of Section 11 of the Aliens Restriction (Amendment) Act, 1919, which imposes restrictions on the acquisition by former enemy aliens of certain kinds of property, have been applied to the following industries, namely, the manufacture of synthetic organic dyestuffs, colours, or colouring matters, and the manufacture of organic intermediate products used in the manufacture of synthetic organic dyestuffs, colours, or colouring matters. The effect of this is to make it unlawful for any former enemy alien to acquire either in his own name or in the name of a trustee any interest in the industries in question, or any share, or interest in a share, in a company registered in the United Kingdom which carries on the industries.

Orders under the German Reparations (Recovery) Act, 1921.—German Reparations Recovery No. 1 Order, 1921.—Any article imported before May 15 is exempted from the provisions of the Act if it be proved (*a*) that a contract was entered into before March 8, 1921, and (*b*) that not less than 20 per cent. of the purchase price was paid before the said date in pursuance of such contract, or (*c*) that the physical possession and property in the article, the subject of the contract, had passed to some person other than a German national prior to the said date.

German Reparations Recovery No. 2 Order, 1921. —This Order extends the provisions of Section 4 of the Act so as to include contracts for resale entered into by importers before March 8, 1921.

Petroleum Production (Transfer of Powers) Order, 1921.—By an Order-in-Council the powers of the Ministry of Munitions under the Petroleum (Production) Act, 1918, and all rights and liabilities acquired or incurred by the Minister of Munitions under that Act, have been transferred to the Board of Trade, such powers to be exercised through the Secretary for Mines.

Export of Industrial Explosives.—The Board of Trade (Licensing Section) has issued an open general licence permitting the export, as from April 14, 1921, of the following explosives:—Rockite, super-cliffite No. 1, super-cliffite No. 2, superrippite, tonite or cotton powder No. 1.

Certificates of Origin.—The following goods, *inter alia*, are exempt from the requirements of certificates of origin:—Marble, limestone, sandstone, ganister, sulphur, iron and copper pyrites, mechanical pulp, and iron and other metalliferous ores and scrap (except from Denmark, Holland, and Belgium). Declarations of non-German origin are still required.

LEGAL INTELLIGENCE.

Breach of Contract for Sale of Soda Products. *John Batt and Co., Ltd.* v. *Aniline Dye and Chemical Co.*

On April 12, in the King's Bench Division, Mr. Justice Shearman had before him in the form of a special case the arbitration proceedings between John Batt and Co., Ltd., London, and the Aniline Dye and Chemical Co., which referred to the breach of a contract for soda ash and caustic soda.

Counsel for John Batt and Co. stated that his client's complaint was that the chemical company had broken its contract to sell to Batt and Co. 400 tons of soda ash and 100 tons of caustic soda; and that under the arbitration proceedings Batt and Co. asked for the difference between the contract price and the market price. The chemical company had failed to ship the goods. The point raised by the sellers was under the red ink clause in the contract, viz., " The price of goods sold under the contract may be advanced from time to time, and the present price of raw materials and the current rate of wages increased owing to the action of the Government; and the buyer shall have the option of saying whether on the advance he will accept it or refuse to have the goods." Counsel added that before the breach of the contract no notice was given by the sellers to the buyers.

His Lordship upheld the arbitrator's award, and ordered the chemical company to pay Batt and Co. £7050 and costs.

COMPANY NEWS.

UNITED ALKALI CO., LTD.

Addressing the adjourned twenty-ninth and the thirtieth ordinary general meetings, held at Liverpool on April 20, Mr. Max Muspratt, the chairman, said that difficulties had been enormously accentuated by the greatly increased cost of all construction, the slowness of delivery of plant, and the high cost of production, especially of fuel and labour. The first had led to an expenditure of several hundred thousand pounds in excess of estimates; the second had delayed the complete operation of more economical processes in time to meet the boom demand; and the third had reduced profits to a minimum. Since trade had fallen off production had been curtailed, and at the present time several of the company's works were completely, and others partially, shut down. On the other hand, deferred repairs had been overtaken and new processes introduced. The Leblanc soda process had been superseded by the electrolytic process. The discovery of brine at Widnes indicated an improvement in the company's position, and since the beginning of this year brine from this source had supplied all the electrolytic plants.

Dealing with finance, Mr. Muspratt stated that during the last six years the company had paid £1,759,233 in taxation, as against £1,847,905 in net dividends, and that £2,500,000 had been spent on plant in accordance with instructions from the Ministry of Munitions. By making certain adjustments of the debenture capital it was hoped to avoid offering any new share capital for public subscription. In spite of considerable profits made in 1920, it was considered unwise to pay a dividend on the ordinary shares. In view of the falling costs of living, proposals had been made to the employees that they should accept reductions in wages. The company was now producing on the best and most economical lines, and a comparatively small increase in the demand for its products would put it on a sound basis of profitable manufacture.

Dr. G. C. Clayton stated that, owing to the coal strike, the works were rapidly starving for coal, and in the course of a few days would have to close down.

THE BRITISH PORTLAND CEMENT MANUFACTURERS, LTD.

At the tenth ordinary general meeting, held in London on April 12, the Hon. F. C. Stanley, chairman, said that in 1920 production, deliveries, and profits of cement had all been better than in any year since the outbreak of war. The difficulties attending manufacture and distribution became less severe during the latter part of the year, and though at the moment there was more than a lull in business, there were indications that the tide had turned, and he looked forward to a revival in the demand for cement. The demand had been very acute during the whole of the past year, and every effort had been made to meet it; if manufacturing cost was high, the average price was good and the profits satisfactory, especially in the export markets. Although prices in the export markets were far above those ruling at home, the company had voluntarily restricted its export sales in order that the great home demand might be satisfied. The output had gradually improved during the year, and at its close was approximately equal to that of the last pre-war year. The Cement Marketing Co., which was formed in 1920 to distribute the company's production and that of certain allied companies, had fully justified expectations.

Whereas the balance of profit brought forward from 1918 was £136,264, subject to excess profits duty, that now carried forward was £181,477, after deducting an ample sum for the duty and the corporation profits tax. The trading profit, less repairs and renewals, taxes, etc., was £558,618, and after meeting debenture interest, etc. and putting £150,000 to general reserve, the balance was £323,406 (issued capital, including debentures, £3,698,080). Owing to the need for conserving resources, the dividend for the year on the ordinary shares would be limited to 15 per cent. (8 per cent. for 8 months in 1919). The capital account had been increased by a large sum representing the value of the three subsidiary undertakings (Tolhursts Cement Works, Ltd.; Trechmann, Weekes and Co., Ltd.; and the Artillery and Albion Cement Co., Ltd.) which had been transferred from the investment account, and a heavy mortgage on one of these had been paid off. In addition, the expenditure of £237,000 on works and properties had been added to the fixed capital account, and provision would have to be made for the works now being erected in India. Owing to these considerations it had been deemed advisable to issue to a financial group the whole of the remaining debenture stock, viz., £509,533, on the basis of an annual yield of 7½ per cent.

SHAWINIGAN WATER AND POWER CO.

The report of the Shawinigan Water and Power Co. states that the capacity of the company's power stations is now about 220,000 electrical h.-p., compared with 20,000 h.-p. in 1905. The company began operations in 1900 and during the last five years the load has grown at an average rate of 20,000 h.-p. per annum. A further 40,000 hydraulic h.-p. will be developed in 1921 and this will lead to an increase in the company's revenue of over $1,000,000 per annum. The output of 1,140,759,076 kw.-hr. in 1920 is only paralleled by one or two other industrial centres in North America. The assets of the company are valued at $34,000,000, mortgage bonds etc. at $13,000,000, and reserves amount to $4,000,000, or, roughly, 20 per cent. of the isued share capital.—(*Canad. Chem. and Met., Mar.,* 1921.)

OFFICIAL TRADE INTELLIGENCE.

(*From the Board of Trade Journal for April* 14 *and* 21.)

OPENINGS FOR BRITISH TRADE.

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents, or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number:—

Locality of firm or agent.	Materials.	Reference number.
Australia	Pottery	*412/20/7/531
Canada	Drugs, etc.	458
,,	Olive oil	461, 483
,,	Pharmaceutical chemicals	468
,,	Glass, china	469
,,	Drugs, etc.	†
Belgium	Ink	497
,,	Machine and industrial oils	498
Denmark	Sugar	503
Hungary	Skins, tanning materials, leather	507
Italy	Agricultural chemicals, fertilisers, soap, varnish, dyes	473
,,	Tinplate, black plates, terne plates	474
Netherlands	Fine chemicals	509
Poland	Tinplate	510
Spain	Chemicals, pharmaceutical products, shoe leather	476
Switzerland	Rubber tyres	477
Mexico	Photographic materials	516

* The Official Secretary, Commercial Information Bureau, Australia House, Strand, London, W.C. 2.

† The High Commissioner for Canada, 19, Victoria Street, London, S.W. 1.

MARKETS SOUGHT.—A Canadian tannery has for disposal 5000 sides of harness leather from 14 to 30 lb. to each side.

A Canadian tannery offers 30 tons of medium wax splits, all shorts, 50 per cent. seconds. [Inquiries to the Canadian Government Trade Commissioner, 73, Basinghall Street, London, E.C. 2.]

TARIFF. CUSTOMS. EXCISE.

Australia.—The application of the new customs duties on soda ash and caustic soda has been postponed until October 1, 1921, and those on iron and steel tubes and pipes [Tariff Item 152 A] until January 1, 1922.

Belgium.—The customs duties have been modified on, *inter alia*, gold, silver, platinum, perfumery, pottery, porcelain, glassware (except bottles, vials, demijohns and carboys).

The maximum "coefficient of increase" which the Government is authorised to apply has been raised to 6; articles upon which it has been increased include candles, cocoa, yeast, matches, certain metals, paper, cardboard, certain hides and skins, liquid carbonic acid, acetic and sulphuric ethers, soap, glass bottles, vials, demijohns, and carboys.

British India.—The complete text of the revised schedule of customs duties is set out in the issue for April 14.

Among the articles that are free of import duty are salt for industrial use, raw hides and skins, metallic ores, certain oilseeds, fertilisers, woodpulp, paper-making materials, quinine, and trade catalogues (by post).

Articles that pay duty at special rates include sugar, salt, petroleum, opium, and matches. Other goods pay *ad valorem* duties varying from 2½ to 20 per cent. The duty is 11 per cent. on chemicals,

drugs, medicines not otherwise specified, dyeing and tanning materials, paints, colours, glass, earthenware, china, leather, paper, cardboard, oils, oilcake, perfumery, pitch, tar, soap, starch, and candles.

Canada.—Recent customs decisions affect circular sheets of steel, and aluminium, copper, brass, zinc, and other metal circles.

Chile.—The new tariff modifications came into force on February 23. The duty is unchanged on condensed milk, raw cocoa, sugar, petrol, paraffin wax, mineral oils (not specially mentioned), prussian blue, and ultramarine.

Among the articles on which the duty has been doubled are chocolate, vinegar, perfumery, and perfumed soap.

As from February 14 the import of opium, coca, cocaine, and substitutes thereof is subject to licence from the Director-General of Health.

Egypt.—Groundnuts and helba may now be exported without special licence.

The tariff valuations of iron and steel manufactures with effect from March 16 to May 15 are given in the issue for April 21.

France and Algeria.—The import duties have been modified on aluminium, celluloid, and bottles.

France.—The prohibition of the export of soap has been withdrawn.

Germany.—The import of oleomargarine and of premier jus is no longer subject to licence.

Do. (Occupied Territory).—The full text of the customs organisation and import and export regulations is set out in the issue for April 21.

Gold Coast.—An export duty of ½d. per lb. has been levied on kola nuts exported by sea, with effect from February 4.

Greece.—Caustic soda may again be imported. The export of olive oil of the present crop is permitted subject to a special licence.

Mexico.—Crude mineral oil, sulphuric acid, blasting powder, and other explosives not specially mentioned may be imported duty free as from March 14.

Montserrat.—Calcium arsenate may be imported duty free.

Netherlands.—Bones, fertilisers, and sugar may now be exported.

New Zealand.—As from January 27 the import of opium, morphine, heroin, and cocaine is subject to permit from the Minister of Customs.

Norway.—The export of all goods is permitted except, *inter alia*, explosives, bones, cellulose, wood pulp, copper ore, cyanamide, gold, silver, hides, skins, leather, nitrate of lime, paper, cardboard, and superphosphates.

Palestine.—The import of opium and saltpetre is subject to special licence.

Portuguese East Africa.—A copy of the new customs tariff for Manica and Sofala may be seen at the Department, 18, Queen Anne's Gate, S.W. 1.

Spain.—The import duty on sugar has been raised to 60 pesetas per 100 kg. as from March 30.

As from April 1 the import duties on the various classes of paper which were suspended in August last have been reimposed.

Sweden.—Export prohibitions have been withdrawn from certain hides and skins, etc.

Switzerland.—The import is prohibited, except under licence as from April 8, of thick leather, calf leather, and other leather for boot and shoe uppers.

United States.—Articles affected by the proposed emergency tariff legislation include olive oil, groundnut oil, sugar, molasses, syrup, flax-seed, and condensed milk.

TRADE NOTES.

FOREIGN.

St. Vincent in 1919.—Cotton was planted on 6633 acres, the largest area ever recorded, and the production was 212 tons, compared with 195 t. in the previous year. The sugar-cane industry is resuming its former importance and the manufacture of syrup has increased considerably; but very little sugar is produced. The production of syrup and molasses was 170,842 gallons. Owing to low prices and large stocks, the area under arrowroot has decreased; only 1002 tons was exported, compared with 2225 t. in 1918. There was also a decline in the area under groundnuts, of which 11,329 bushels was exported. The Agricultural Department has continued its work on cotton breeding, on the production of supplies of pedigree Sea Island cotton seed, and on the manuring and planting of cotton and arrowroot. The exports, valued at £149,749, included:—Arrowroot, £42,222; cotton, £66,782; syrup and molasses, £10,726; cassava starch, £4836; and groundnuts, £5098. Over 58 per cent. of the exports was taken by the United Kingdom, 27 per cent. by the British West Indies, and 8·7 per cent. by Canada. Of the imports, valued at £185,128, the United Kingdom, United States, and Canada supplied 31·4, 29·2, and 29·6 per cent., respectively (*cf.* J., 1920, 404R).—(*Col. Rep.—Ann.*, No. 1063, *Feb.*, 1921.)

German Exports to England.—German exports to England increased greatly during the last six months of 1920; during the third and fourth quarters of the year they included:—Dyestuffs, £1,000,000, £3,040,000; glass bottles, £127,000, £164,000; crude zinc, £67,000, £315,000; and raw sugar, £12,000, £240,000.—(*Handelsmuseum*, *Mar.* 31, 1921.)

The Japanese Dye Market.—Increased activity followed the introduction of the new import tariffs in August last, but so long as the weaving sheds are working short time it is unlikely that consumption will equal supply. Towards the middle of November there was a general rise in prices with the exception of Malachite Green, Sulphur Black, and Basle Blue. The suggested amalgamation of Japanese dye makers will probably not materialise; some of them, apparently, only desired it in order to avoid liquidation.—(*Chem. Ind.*, *Mar.* 28, 1921.)

Foreign Company News.—*Poland.*—The Polish Dyeworks Company, recently founded in Wierzchucin-Krainski, near Bromberg, has purchased a disused factory, and will manufacture mineral colours, lakes, and varnishes.—(*Chem. Ind.*, *Mar.* 28, 1921.)

Holland.—The Netherlands Dyestuff Factory has been formed in Amsterdam by certain Dutch banks and chemical firms to manufacture and trade in dyewares and other chemical products. The capital is 5 million florins (florin=1s. 7·8d. at par).

Germany.—The new Distillers' Yeast Syndicate, founded in March, represents nearly 95 per cent. of the German production, the combined output of its constituent firms being about 37,500 metric tons. The syndicate (Brennerei-Hefesyndikat G.m.b.h.) will fix prices and control sales, and it is expected to be much stronger than the former combine.—(*Handelsmuseum*, Mar. 24, 1921.)

France.—The Cie. Industrielle des Verreries à Vitre (capital 14·9 million fr.) is building large works at Cussett, in Allier, to manufacture window-glass by the Fourcault process on a very large scale. The company has taken over the Verreries Valentin Mesiner at St.-Etienne, and has also acquired the Aniche works of the Société Industrielle de Verrerie.—(*Bd. of Trade J.*, *Mar.* 24, 1921.)

Japan.—The formation of a combine of Japanese producers of sulphur colours, initiated by the Teikoku and Kompira dye companies, has made further progress, and a commission has been appointed to investigate the financial status of 18 firms producing sulphur colours in Tokyo, of which the total paid-up capital is about 4 million yen. If the combine is effected a new undertaking will be formed with a capital of 6 million yen.—(*Chem. Ind., Mar.* 21, 1921.)

United States.—A new company entitled "The Industrial Potash Corporation" has been formed with a capital of 30 million dollars to exploit the extensive alunite deposits near Marysvale, Utah, and to erect a plant to treat some 10,000 t. of material daily, mainly with a view to producing potassium sulphate for agricultural purposes.

It is reported that the Du Pont Co. is considering plans for the erection of a dry-colour plant to be the largest in the world, and to add a new paint and varnish plant to the existing units.

The capital of the Allied Chemical and Dye Corporation is to be increased from $48,043,675 to $113,043,675.—(*Oil, Paint and Drug Rep., Mar.* 14, 1921.)

Norway.—With the exception of the cellulose factories and the Norsk Hydro-Elektrisk Kvaelstof A.-S., Kristiania, which manufactures Norwegian saltpetre and ammonium nitrate, all other chemical and allied undertakings have been forced to curtail production or to close down. Three firms in the carbide industry have ceased to produce and the remainder are working at 30—40 per cent. capacity. About 40 per cent. of the mines is being worked. The Glomfjord zinc-smelting works, a private undertaking run largely with Swedish capital, has suspended operations, and it is reported that negotiations for its sale to English interests are proceeding.—(*Chem. Ind., Mar.* 14, *Apr.* 11, 1921.)

Sweden.—The net profit for 1920 of the Svenska Tändstiksfabriks A.-B., which comprises the majority of the Swedish match factories, was 12,950,000 kronor (krona=1s. 1½d. at par), and the dividend 14 per cent. (capital 45 million kr., reserves 65 million kr.). The production of 600,000 cases represents about 20 per cent. of the world's output; the turnover was 105 million kr., of which 95 million kr. was in respect of foreign sales. Prospects are now more favourable, as Japanese competition is much less keen than it was before the war. Owing to the high exchange value of the yen the Trust has been able to capture the Indian market, and in Australia racial feeling has told against the Japanese. The Trust anticipates that by April its stocks will have fallen to a normal level.

The liquidation is announced of the well-known oil-mill and soap works Malmö Oljeslageri and Happachs Sapfabriks A.-B., Malmö, and at the same time the formation of a new company bearing the same title with a capital of 1·5 million kr. The Barnängens Kemiska Fabriker in Stockholm and Hudiksvall has also failed, but work is to be continued. The projected absorption by Lever Bros., Ltd. of various Swedish soap factories may be regarded as definitely abandoned, but the formation of a combine within the country which will command about 90 per cent. of the entire production will be shortly effected. Companies producing superphosphate, paper, sulphite pulp, and iron ore have announced a partial or total suspension of operations. Unemployment is greater than during the early part of last year.—(*Chem. Ind., Mar.* 18, *Apr.* 11, 1921.)

The Soap Industry in Argentina.—In 1910 there were 200 soap factories in Argentina, having a total capital of £219,214, with an output valued at £602,860, and utilising imported raw materials worth £114,789. Since then the demand for soap has increased, production has risen, and importations have declined from 1795 metric tons in 1913 to 1371 t. in 1919. Hard yellow soaps are mainly produced as they are in greatest demand, but their quality is poor. With the exception of animal fats, all the raw materials are imported. In 1919 the United States supplied nearly all the rosin, nearly one-fifth of the soda ash, over 70 per cent. of the caustic soda, and about 5 per cent. of the sodium silicate. American silicate of soda has been criticised on grounds of quality and price, and the European product is preferred. The total importations in 1919 were:—Rosin, 15,503 metric tons; soda ash, 3459 t.; sodium carbonate, 1570 t.; Solvay soda, 5878 t.; caustic soda, 6543 t.; and sodium silicate, 4512 t. There is a steady demand for coconut and palm oils, perfumes, and colouring matters. —(*U.S. Com. Rep., Feb.* 18, 1921.)

The Phosphate Industry in Curacao.—According to *De Telegraaf* of March 8, the position of phosphate mining in Curacao is favourable, despite the emigration of a number of miners to Cuba. During 1920 64,969 tons was exported, distributed as follows:—Sweden, 28,505 metric t.; Germany, 15,758 t.; Holland, 10,566 t.; Spain, 2946 t.; England, 2113 t.; and Norway, 508 t. Exports during previous years were:—1915, 31,308 t.; 1916, 14,468 t.; 1917, 3582 t.; 1918, nil; and 1919, 19052 t.—(*Official.*)

REVIEWS.

Application of Dyestuffs to Textiles, Paper, Leather and Other Materials. *By* J. Merritt Matthews. *Pp.* vi.+768. (*New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.* 1920.) *Price* 10 *dollars.*

English readers have had abundant opportunity during recent years of becoming familiar with American publications on technical subjects, and will find that the present volume displays most of the points of excellence which they have learned to expect. The book is admirably bound, printed, and illustrated, but the text does not approach the standard of those English works on the subject with which it challenges comparison. The major portion of the work deals with textiles and includes sections on the chemistry of the textile fibres and the processes of scouring, bleaching and the like, as well as of dyeing. The treatment of these subjects is such as to form a suitable groundwork of instruction for pupils in technical schools. Each chapter concludes with an account of experiments which are very well devised for illustrating and impressing on the minds of students the points dealt with in the earlier part of the chapter, and the whole collection of experiments would form an admirable laboratory guide in the study of the subject. The arrangement of subjects in the text is such as to involve frequent repetition of the same statements, although with a different lay-out of the subject matter considerable space could have been saved. The details of works practice and the special precautions to be taken in work on a large scale are very inadequately treated. This is the more to be regretted because the book contains more numerous and excellent illustrations of machinery than the writer remembers having seen in a work on this subject. These illustrations, however, are for the most part not referred to in the text, and many of them are quite outside the scope of the work. Regarded as a text-book for students, the book appears to be rather too dogmatic and too little suggestive and stimulating to

thought. The author is disposed to give explanations which strike one as merely facile. Such explanations may have some value as mnemonics, but it is doubtful if they are calculated to encourage a scientific habit of mind or lead to a sound knowledge of the subject. The treatment of such subjects as the application of sulphur colours and of mordant dyes on silk leaves a general impression that the dyeing industry in America has not reached so advanced a stage as in this country.

The book contains some useful summaries of the special properties of dyestuffs, and much information which can be found elsewhere only in a scattered form is here collected together very conveniently for reference. There is a copious bibliography.

In conclusion, this book can be recommended as a useful addition to technical libraries on account of its excellent illustrations and summaries as well as for the admirably devised series of illustrative experiments.

Benjamin Leech.

Water Purification Plants and their Operation. *By* Milton F. Stein. *Second edition. Pp.* 270. *(New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.* 1919.) *Price* 16*s*. 6*d*. *net.*

The second edition of this book has recently appeared, and contains new chapters on bacteriological tests for water and their interpretation.

The fact that the book deals almost exclusively with American waterworks, where the problems to be faced are to a great extent different from our own, very considerably curtails its usefulness in this country, and the further fact that the chapters on chemical and bacteriological tests and their interpretation are written by an engineer for non-technical men is also a decided disadvantage. It certainly does not seem wise that the chemical and bacteriological tests of such an important commodity as drinking water should be entrusted to anyone but a trained chemist or bacteriologist, and only a sanitarian should have the duty of interpreting them. The risk involved is too great; an error in carrying out the tests or a faulty interpretation of the results might open the way to very considerable trouble. Apart from this general principle, the author's treatment of this part of the subject leaves much to be desired. No mention is made in the chemical tests of any test for organic impurity such as free and albuminoid ammonia, or oxygen absorbed from permanganate, which are still insisted on by English sanitarians, and which are undoubtedly of great value when properly interpreted. The bacteriological tests given are also somewhat crude, although, as in the chapter on chemical tests, elaborate details are given of the apparatus required. The tests consist of the gelatin and agar counts and the litmus-lactose-agar, and lactose-broth tests for intestinal microbes. The latter tests would include many non-intestinal microbes, and to this extent err on the side of safety, but to the scientific mind something more exact would be preferable. A word may here be said on the difference between English and American standards. The Americans seem to be content with a standard based on percentage reduction, whilst in this country an absolute standard is generally insisted upon. Thus, if the raw water contained, say, *B. coli* in 0·001 c.c., and in the finally purified effluent this was reduced to a positive result with 1 c.c., they would call this a 99·9% reduction and be satisfied with it, but in this country we are not completely satisfied with sending water into consumption even with *B. coli* in 100 c.c.

This review has dealt chiefly with the chemical and bacteriological parts of the book, as they would seem to be those of most interest to members of the Society of Chemical Industry, and to that extent is adverse criticism: but much of the book is excellent.

Following an introductory chapter on sources of supply, a long chapter is devoted to detailed engineering descriptions of typical plants in the United States, covering all methods of purification. After the chapters on chemical and bacteriological tests, coagulation and sterilisation are carefully dealt with. The theory of coagulation and the chemical reactions of the coagulants are discussed, and numerous plants for the addition of chemicals are described. Then follow interesting chapters on water-softening, sedimentation, filtration, and general operation, and some graphic charts for calculating quantities of coagulants, etc. required under diverse conditions. These, by the way, are drawn for U.S. gallons, which are smaller than the imperial gallon.

The book concludes with appendices dealing with the analysis of coagulants, instructions for making standard solutions, and specifications for certain chemicals. It is profusely illustrated with sketches, photographs and working drawings, and is written in a clear and readable style.

D. B. Byles.

Rubber, Resins, Paints and Varnishes. *By* R. S. Morrell *and* A. de Waele. *Industrial Chemistry Series, edited by* S. Rideal. *Pp. xii*+236, *with 33 figures in the text. (London: Baillière, Tindall and Cox.* 1921.) *Price* 12*s*. 6*d*. *net.*

This is yet another of the voluminous stream of recently published books belonging to what one is tempted to classify as the "Science-in-a-Hurry" type; books which, unfortunately, bear the obvious marks of hasty compilation and of lack of the care which is to be expected in scientific text-books.

The first part of this book deals with rubber, and occupies only 34 pages. Even allowing for unavoidable defects due to the extreme brevity of this section, one is compelled to state that it is lacking in accuracy and that the information given is not so well selected or arranged as it might have been. Considering the great importance of rubber both from the scientific and technical points of view, it is perfectly obvious that nothing adequate could have been written in so small a space, and that this subject should have been given a volume to itself. The remaining sections of the book dealing with drying-oils, resins and pitches, pigments and paints (including linoleum), and varnishes, are more satisfactory, though at times lacking in discrimination of the relative importance of the different subjects dealt with. Thus, it is difficult to understand why, in an elementary industrial handbook, more than six pages are devoted to the analysis of varnish (a complex subject which is obviously dangerous ground to the student), whereas less than three pages are given to the analysis of oils, and paint-analysis does not appear to be even mentioned.

This volume, in common with others of the series, is apparently intended largely for the advanced student, and it will certainly be of some value to readers requiring to obtain with a minimum expenditure of time and labour a general idea of the subjects dealt with. It is, perhaps, open to discussion whether such books are not somewhat dangerous to the student, as being calculated to lead him to accept short-cuts and easy paths to knowledge when he ought to be learning how to consult standard books and original papers. One must, however, admit that the authors have made

some allowance for this in giving a short but useful bibliography of the subjects and fairly frequent references to journals, etc.

The reading of this book (particularly the first part) brings to notice a too-frequent fault in chemical and technical literature, *i.e.*, the misquotation and mis-spelling of botanical names; there is no more excuse for these faults than there is for errors in chemical formulæ. Authors and publishers would do well to attempt to obtain accuracy in botanical nomenclature.

RUSSELL G. PELLY.

JOURNAL OF INDIAN INDUSTRIES AND LABOUR. *Vol. I., Part 1. February, 1921. (Calcutta: Superintendent, Government Printing, India. 1921.) Price Rs. 1–8 per part, or Rs.4–8 per volume of 4 parts.*

The publication by the Government of India of a new journal devoted to Indian industries and labour is further evidence of the increased attention which industrial development is now receiving in that country. In a "Foreword," Sir Thomas Holland explains that the Journal has been established to function as a bond of union between those responsible for the machinery of development in the different provinces of India in which policy and natural resources may also be different. At the same time it is also intended to act as "a medium for communicating to a wider public, within and outside India, information that will assist private enterprise."

To the number under review Sir C. E. Low contributes a particularly interesting article on "Possibilities of Industrial Development in the Central Provinces and Berar." Although chiefly concerned with the future outlook for these territories, many of the difficulties and problems dealt with may be taken as affecting the industrial development of India in general. Mr. B. M. Das, writing on "Researches in Tanning and the Calcutta Research Tannery," describes the organisation and objects of an institution which should do much to place this industry, of so great importance to India, on a sound scientific basis. Dr. J. Coggin Brown's "Trade Notes on Bauxite," whilst applicable more particularly to Indian conditions, are also of general value. Mr. S. T. Gadre describes the results of an investigation on "Clove Oil from Clove Stems," and discusses the possibility of carrying out the process of extraction on a commercial scale in India. An article by Capt. G. N. Frankau on "The Gilt Wire and Tinsel Industry at Burhanpur" affords an illustration of an old industry, by no means the only example in India, which has fallen into decay chiefly through the antipathy of the worker to adopt machinery and modern methods and thus meet European competition. Papers dealing with "Welfare Work in Bombay Cotton Mills," "Trade Disputes in Bengal," and "Industrial Education in Madras Presidency" are all of interest as serving to show that the development of industry in the East has given rise to problems similar to those which are still occupying the attention of the Western world. The Journal also contains a useful summary of Industrial Intelligence from the various districts and some Miscellaneous Notes.

In addition to the Journal, the Government of India announces the publication of Bulletins of Indian Industries and Labour, uniform in size with the Journal, and intended to deal with specialised subjects in monograph form.

It may be confidently predicted that if the high standard set by the first number of this Journal is maintained, the objects of its publication as set out therein will be fully achieved.

A. RULE.

OBITUARY.

A. WYNTER BLYTH.

Alexander Wynter Blyth was educated at King's College, London, and practised as a physician for a few years in Worcester before he became Medical Officer of Health and Public Analyst for the County of Devon. From Devonshire he came to London and filled a similar position to the Borough of St. Marylebone. Associated for many years with the Sanitary Institute, he served on its Council, was chairman of its judges, and latterly hon. registrar. A past-president of the Society of Medical Officers of Health, he was for some years editor of "Public Health," and had much to do with the foundation of that journal. He contributed papers on sanitary science, law (he was also a barrister-at-law), and the chemistry of foods and drugs to the learned societies, and was the author of two well-known books, "Foods: their Composition and Analysis," and "Poisons, their Effect and Detection."

Wynter Blyth died on April 1 last in his seventy-seventh year.

POST-GRADUATE TRAINING IN INDUSTRIAL CHEMISTRY.*

FRANCIS H. CARR.

In recent discussions concerning the training of chemical students for industry there is to be traced a unanimity of opinion as to the need of modifying or extending existing courses of instruction, at least so far as concerns the education of certain classes of chemists required in the industries, especially the fine chemical industries. Notwithstanding this, it seems that too little is being done to bring about the necessary changes. The difficulty of finding the money required for equipment and endowment is illustrated in the case of the Department of Chemical Technology of the Imperial College of Science and Technology. In my humble opinion this college needs an expenditure of several hundred thousand pounds in order that the Department may properly fulfil its great national purpose. The difficulty of getting money does not lessen the need of it, but imposes upon those in whom the war has awakened the full realisation of our shortcomings the serious duty of explaining our needs.

A strong alliance between the universities and the industries is now regarded by all as advantageous to both. The industries have in the past undervalued the importance of the part which the universities play in the fulfilment of the national purpose, by aiding the development and progress of industry. The universities depend largely upon the demand for training created by industry, and a little thought must convince all that even the pursuit of pure research must ultimately depend upon the value of its results to the physical, mental or moral well-being of humanity. On the other hand, the future development of industry lies with the trained and selected men from the university, and in the special case of the chemical industry, much depends upon the work done by the university in giving the right direction to science students, and providing the right training for each type.

If a discussion becomes discursive, it is apt to prove barren; I will make, therefore, a few hypothetical assumptions and rule these out of the discussion. The first of these assumptions relates to the curriculum for graduation in science; although I would like to see this modified in minor details, let us assume for the moment that it constitutes the desired foundation for those taking up a career in chemical technology. Secondly, let us assume that a three years' course with chemistry as the principal subject does not qualify a man in technical chemistry. It is regrettable that there should be a general feeling abroad, especially among parents, that graduation, which normally occurs in the third year, implies fitness for practice. A student has to work hard enough in all conscience during his three years in order to merit a first-class B.Sc., without spending any time upon the cognate subjects required to qualify him as a technical chemist. It becomes, therefore, a question of post-graduate training. Do we need the colleges to undertake this?

There are those who hold that since some firms are willing and able, and indeed prefer, to train their own men, there is consequently no need for intra-mural training in chemical technology. My comment upon this is that there are only a few firms fitted to undertake this work, and these few certainly are not willing to train men for the many other firms who cannot undertake to do so; and it is these unfitted firms which offer the greatest scope to the young technical chemist. The number of young chemists who are fortunate enough to gain admission to the works in which good training may be found is insufficient for a rapidly-developing industry, and even these men would gain much by attending a properly constituted course prior to the works training referred to. It is not all, or even most, of the chemists employed in works who need a special technological training, and only a small proportion of those who adopt chemistry as a career have the real instincts of the chemical technologist. Chemists not possessing this instinct may excel as workers in one or other of the works' laboratories, whether it be in that concerned with process-control, research or analysis. The technical chemist needs other qualities, such as ability to give directions when a reaction takes a course different from that expected, ability to accumulate experience of practical detail, to make yields higher and higher, to reduce the cost of labour more and more, and carefully to harvest from daily observation all those deductions which become summarised in a perfected process. Such power of controlling complicated and delicate processes, not merely conscientiously, but with intelligence and initiative, of observing closely and appreciating what in a mass of observed details is of practical importance, demands qualities of mind which are different from, though not incompatible with, those of the research chemist, although both types usually excel in the laboratory. These qualities are inbred, you will tell me, and are not produced by education. True enough; but the development of these qualities may be enormously helped by a training in certain subjects not gained during a three-years' course, or during the longest sojourn in a research laboratory. The industrial chemist may have the research instinct, and he will not need to starve it, but his hunger after new knowledge for its own sake must not prevent him from giving his interest and great enthusiasm to minute questions of economy, to the choice of the cheapest materials, to labour-saving devices, thermodynamic considerations, questions of fuel economy, and so forth. Such work demands not merely a type of ability as specialised as that of the research chemist, but, above all, a specialised type of training which it is our business now to consider.

In speaking of the technical or industrial chemist, I have in mind, perhaps, a more particular type of man than the actual expression implies, namely, the person who gets to grips with the actual chemical or industrial process carried out on the large scale; in this country the heavy chemical and metallurgical industries, as well as those concerned with the production of fats, oils, soaps, starch, sugar, tanning, etc., have on the whole been moderately well developed, and have in many respects even excelled. In the synthetic organic chemical industries, on the other hand, the elaboration of residuals, the manufacture of intermediates, dyes, photographic chemicals, drugs and the like, have not, prior to the war, succeeded, and we have been outstripped by foreign competitors. I think we may find in this distinction some indication as to the line we should pursue in education in order to remedy the latter condition. In the organic chemical industries there is a great diversity of operations involving expert knowledge; frequently the demand for the product concerned is on such a scale that its manufacture cannot be carried on continuously all the year round, so that the diversity of functions required for individual manufactures—much more complicated than in the case of the first-mentioned class of substances—is still further extended by the making of now one compound and now quite a different one. The operations require a very close

* Paper read before the Old Students' Association of the Royal College of Science, Feb. 8, 1921.

attention to details, and quite small variations of conditions may entail great reduction of yield and result in financial losses. Now, those responsible for the supervision of such work must not only be skilled, but highly educated men of a particular type who, when produced in this country, hitherto have been self-trained and not the direct product of the university; but I suggest that it is not only possible, but of urgent importance that we should give a suitable training for this purpose. It is true that the right men are few, and it therefore takes a big net to catch them. It would surely be of immense advantage if students admitted to any such post-graduate course in a college were graduates widely drawn from the various universities of the country. Such moving about might with great advantage be encouraged more than it is.

Chemists in the heavier industries referred to above can in a large measure carry on their work from the laboratory and the office, giving instructions to the foreman whose rule-of-thumb knowledge constitues a very real bulwark, but in the manufacture of fine chemicals processes need to be directed by a chemist on the spot. This chemist must be a man who inspires confidence, and can act with courage born of conviction. A man who not only knows, but who knows that he knows, and, above all, a man willing to don overalls and to dignify his works and himself by practical co-operation on the plant.

If you will take the view that for such positions men can, by training, become better fitted for the work earlier in life, what is the nature of the training required? A sound fundamental knowledge of chemistry, physics and mathematics is a condition of graduation; super-added to this must be a not inconsiderable training in engineering, machine construction and machine drawing; together with knowledge of fuel economy, chemical kinetics, thermochemistry and electrochemistry, works management, costing and accountancy, and chemical economics. By the last-mentioned, I mean a study of the efficiency of established processes, *e.g.*, alkali, acid and explosives manufacture, and nitrogen fixation from a point of view well illustrated in the Government publications relating to the achievements in war factories during the war. The historical review of these processes would constitute an admirable basis for a course of study. These may be treated as classroom subjects, but they cannot be effectively studied without very special practical training in a technical-chemical laboratory. Such a laboratory would preferably be nothing less than a manufacturing undertaking, but it would not deal with specific manufactures, such as sulphuric acid or soap or brewing or dyeing, as these may be regarded as the function of trade schools which are able to undertake useful teaching of a different kind.

I wish particularly to emphasise the point that there are special underlying principles relating to the application of chemical science to manufacture which can be taught and be of excellent educational value. It may be argued that a one-year's curriculum is all that is absolutely essential, but to this I am not personally inclined to agree; however, the courses might conceivably be so arranged as to leave the way open for some students to break off at the end of the first year, while others spend a second year at laboratory work. I believe, however, that a second year would prove of inestimable value and be readily adopted by students.

In addition to the general classroom subjects referred to, I would make provision for courses of lectures and reading on groups of chemical subjects somewhat as follows:—

(1) Dyestuffs, synthetic drugs, essential oils, sugars, alkaloids, biochemistry;

(2) Coal tar, petroleum, fatty oils, alkali, and acid;

(3) Colloid chemistry, rubber, tanning, cellulose; students being expected to take at least one of these courses.

The success of all attempts to teach chemical technology will depend, however, chiefly upon the opportunity to put knowledge into practice in the laboratory, to develop initiative, resource, and self-reliance in dealing with processes, and in translating laboratory experiments to works-scale manufacture. Often does it happen that a chemist believes a foreman's method to be capable of improvement, yet he has not the varied experience which will justify him in interference, and thus his initiative is discouraged and suppressed. It must be remembered that the majority of foremen secretly resent improvements introduced by another, and will even resort to trickery to render unsuccessful any modification of process suggested by a chemist.

Now, manufacture cannot well be carried on in the laboratory unless the goods manufactured are going to be made use of in one way or another. There are both psychological and practical reasons for this. Materials must be used, and the cost of them, unless the finished product be sold, is a serious deterrent to free experiment; further, a student is not satisfied to expend care on producing a substance which will be wasted and will not come before the tribunal of public criticism; nor would it be good for him if he could be induced to work regardless of these factors.

The scheme advocated consequently involves the formation of a technological teaching laboratory of a new type, one which would be a miniature manufacturing establishment associated with a college providing the necessary lectures and class-room instruction.

In addition to chemical manufacture, technical-scale experiments extending the results of investigations in research institutions or elsewhere might well be undertaken; one would expect that there are enough small demands for compounds not supplied in the ordinary way of trade, as well as for these technical scale experiments, to keep such a college laboratory perpetually engaged in useful work. The compounds manufactured would include such of the less common compounds of rare application as the manufacturer will not be troubled to supply, because the demand is too small and irregular. This manufacturing laboratory would need a permanent staff of experienced men who would act as demonstrators and take a personal part in the practical work. The laboratory would need to be run under conditions of strict and complete business organisation and discipline, with long hours of attendance. Powers practically equivalent to that of dismissal would be entrusted to those in control, and no student would be permitted to proceed from one stage in his course to another without having qualified in the earlier one.

1. Structurally the laboratories would consist preferably of a lofty shed about 27 ft. high, of steel construction, well lit and ventilated, the steel being arranged so that staging may be erected at 9 ft. and 18 ft. from the floor, in which technical-scale plant can be rapidly erected. The successful use of this laboratory would in large measure depend upon the provision of standardised pans, covers, columns, and stills, which can be rapidly fixed in position, such engineering work being chiefly carried out by students

This laboratory might well contain a few special plants designed for typical manufactures suitable for determining efficiency on short runs, such, for instance, as nitro-toluene, formaldehyde, phosgene, ammonia oxidation, benzoic and salicylic acid, the products from which would be utilised for further processes.

2. A large kitchen laboratory fitted with small apparatus of 50 to 100 litres capacity, including typical centrifugal filtration and evaporation plant,

autoclaves, hydraulic press, and so forth. This building should also preferably be a single storey building, and contain a good laboratory for investigations of a preliminary character.

3. The drawing office, library and administrative offices, stores, and the analytical and physical laboratories, each separate rooms, might be included under one roof.

4. The workshops—wood and iron—foundry and forge, and plumbing shop would constitute another departmental group of buildings.

5. A power plant, generating steam, gas, and electricity under conditions which enable a daily computation to be made of the efficiency of each is an essential adjunct. The steam, gas, and electricity would be distributed to separate sections under a scheme of meters to enable the various operations to be accurately assessed with the consumption.

The fundamental object of the instruction would be to introduce the cost quantity in relation to power, heat, labour, cost of material, and yield of product. The observance of these principles concerns the chemical industry more especially than any other, because in that industry costs may vary over an enormous range according to the care and skill exercised. To assist the student in this attitude I consider instruction in practical accountancy, costing, and stock-keeping to be of fundamental and first importance. The care, initiative, and resource which need to be exercised, the practice in approaching problems on economic lines, and the practical knowledge gained, combined would constitute an admirable preparation for industrial management in many spheres, by no means confined to organic chemicals.

During the first year the student would attend courses of instruction in physical and electrochemistry, construction, and design, chemical engineering, and machine drawing. He would also receive practical instruction in the workshops, power-house, analytical laboratory, administrative office, and in the use of special machinery and plant. He would take his turn at stoking, engine driving, plant erection, lead-burning, the making of steam joints, and so forth.

Passing into the works laboratory, first-year students would at first manufacture simple compounds, and be given an opportunity of assisting the operations of advanced students. These manufactures would need to be conducted under strict discipline as regards both time spent and quantitative results, and although from its nature the work would not be on the full scale of ordinary technical procedure, it would be carried out on a sufficiently large scale to require manufacturing apparatus as distinguished from that of the laboratory. During the first and second year the student would become gradually familiar with the construction and use of autoclaves, large reaction vessels, vacuum pans, gas compressors, furnaces, centrifuges, and filter presses, and would acquire experience in handling difficult substances, in utilising catalysts, etc. He would also have experience in designing special pieces of plant for particular technical processes. The courses of lectures would include steam-raising and power production, every student spending several weeks in the department concerned with the supply of steam and power to the institution, and in a laboratory in which fuel, water and flue gases, etc. are analysed. Courses of instruction in special manufactures, such as sulphuric acid and alkali, as already stated, would probably find their places in the curriculum; arrangements might be made for students destined for particular industries to attend special courses of instruction given by men actually engaged in the industries in question—a proceeding which has already been adopted in the evening classes of some of our technical colleges.

Further, it would be an invaluable adjunct to such a college if arrangements could be made for students to attend courses of practical instruction in actual works. By careful arrangement this might be done with such slight interference to the business of the firms concerned during only a short period in each year, that the opposition to receiving such visitations would be satisfactorily met. Above all, it is essential that the staff of the college should consist mainly of men of ripened works experience—not, be it understood, men (however able) who have merely spent a period in the research or analytical department of a works. Such men have usually been regarded by our educational authorities as men with works experience, when in point of fact often they have little or no real claim to a knowledge of chemical manufacture.

As regards the nature of the substances manufactured, the first-year students might be occupied partly in making from the raw material simple inorganic and organic substances; for instance, potassium dichromate and permanganate, metallic arsenic and tellurium, hydrogen peroxide, hydriodic acid, ammonium persulphate, nitrations, sulphonations and the like organic operations, and partly in isolating and purifying tar products, sugars, and natural vegetable products, such as theobromine and caffeine.

In the second and succeeding years—for it may safely be assumed that many students would remain even longer than two years, and it should prove possible to pay them to do so—the students would be occupied chiefly in carrying out large-scale technical research; they would be enabled to follow each other's processes, being present to watch critical stages. The compounds manufactured would, in general, be those which, while not in common use, are required for exceptional purposes, chiefly by colleges and research laboratories. In order that the scale may be a large one it would be necessary to make of many substances much bigger quantities than are likely to be required; these might remain in storage for many years, and only gradually would a complete list of substances in demand be accumulated.

One claim for this scheme is that, besides affording a really practical training, it would maintain and impart by means of actual manufacture and sales a standard of industrial efficiency almost impossible of attainment without this incentive. It would also have the practical value of supplying many chemicals for which we were formerly dependent upon Germany. Nor need we fear that such a scheme would give serious offence in commercial quarters, for the monetary value of business in the manufacture of fine chemicals of this type is of no great account, and it would not be difficult to avoid jealousies by confining the manufacture to those substances which manufacturers of fine chemicals do not wish to produce, and by rigorously adhering to a scheme of distribution through existing trade channels. If a manufacturer should complain that he is subjected to unfair competition through the production of a certain chemical by an endowed and privileged institution, the reply is simple: Let him produce a supply of the substance of adequate purity, and it may be assumed that the college of my conception would leave it to him.

Incidentally, the college would prove of great advantage to research workers, who would have here facilities for procuring the compounds with which their investigation commences, instead of spending much of their valuable time in repeating tedious preparations on a small scale. This single benefit, increasing as it would the effectiveness of research workers, would react favourably on the industry as a whole.

It may be objected that the student cannot lengthen his course at college by a further period of two years. A medical student does not become

qualified in less than five years. Why should a chemical technologist expect to do so? I venture to think he would have to apply himself just as strenuously to achieve what is required of him in the time. The two years would be spent much more effectively from the point of view of increasing the student's monetary value than any other two years of his education, and so far as many are concerned, more profitably than if spent on research.

As to the financial aspect of the scheme, it may be agreed that as manufacturers would gain much they should be looked to for assistance. With chemical industry threatened as it is at this moment, one hardly dare look for much help in this quarter; nevertheless, one might confidently expect that when successfully established the fine chemical industry would afford a substantial contribution towards the maintenance, but the equipment must be costly and the buildings substantial. Surely for this we must look to the Government, whose duty it is to direct our educational organisation with a greater bias to practical ends. Enough to build and endow such a college many times over would have been saved during the war from the vast expenditure on chemical war factories had we had the foresight to establish the fine chemical industries here previously, and a dozen students from a college such as that which I have endeavoured to conjure to your minds might have saved millions. But these millions will only be truly lost if, failing to learn the lessons of the war, we allow our fine chemical industry to slide back to the condition in which it was when war commenced. We escaped disaster once; be sure we should not so escape again.

A BELGIAN BUREAU OF CHEMICAL STANDARDS *

Scientific and Technical Importance of Very Pure Chemical Substances.—It is well known that the purity of materials plays an important and often an indispensable part in many branches of science and technology. Thus the individuality of many chemical types can only be established by preparing very pure elements, and such work has lead to the discovery of numerous elements (*e.g.*, rare-earth elements, rare atmospheric gases) and of entirely new classes of compounds (thiophen an impurity in benzene). Certain physical properties can only be determined by employing pure substances (super-conductivity of metals in liquid helium), and others are inseparably associated with the presence of certain definite impurities (phosphorescence). The progress of stoichiometry depends above all on the investigation of the constants of chemically pure substances. In metrology there is a tendency to replace the use of standardised instruments (metre scale, standard thermometer, etc.) by the adoption of selected constants of well-defined substances. The use of very pure products has also become equally indispensable in technical work, for example, for analytical reagents and the fundamental constants of alcoholometry (density of absolute alcohol); electrolytic copper; pure gases in large-scale catalytic processes; and in biology and medicine, the use of very pure chloroform as an anæsthetic, and of very pure sugars for certain bacteriological cultures.

How can they be obtained?—Both chemists and physicists are often held up in their work by difficulties in obtaining specimens of very pure materials essential to their investigations. Except in special cases, sufficiently pure substances cannot be purchased, whilst those obtainable have to be purified and their purity established. But the purification of small quantities of substances is often very difficult and the criteria of purity are not sufficiently sensitive; the preparation of larger quantities would save much trouble, *e.g.*, in the case of mixtures of isomers or homologues. All physical chemists know, for example, the great amount of work entailed by every worker having to prepare such a substance as pure normal pentane. The war, finally, has much increased these difficulties by diminishing the availability of materials required in the preparation of pure substances.

Such considerations as these have been occupying the minds of chemists in the United States and Germany, even during the war, and have led them to take steps to fill in the *lacunæ* and thus make their work easier, more expeditious and more fruitful.

What has been done in the United States and in Germany.—The Physikalisch-Technisches Reichsanstalt at Charlottenburg has undertaken to make "normal" metals available to German chemists. Research has shown that metals sold as "pure" frequently contain more than 1 per cent. impurity; that it is impossible to prepare on an industrial scale, and without undue trouble, specimens containing less than 0·01 per cent. impurity; and that such substances—classed as grade 4†—suffice for the determination of atomic weights. The Reichsanstalt has therefore initiated a series of researches with the object of determining industrial processes of purification and methods of analytical control. Once these have been worked out, the preparation is entrusted to an industrial firm under the control of the Reichsanstalt, and the specimens are sold with a guarantee of purity certified by it. Similar arrangements have been made with regard to mercurous sulphate (for the Weston cell).

In the United States an analogous task has been undertaken by the Bureau of Standards at Washington, which prepares and sells specimens of alloys and minerals of known composition for analytical control, pure metals for thermometric standards, and certain organic compounds of which the method of purification is minutely described: naphthalene and benzoic acid for calorimetric standards, ammonium oxalate and dextrose for analytical work, and cane sugar for polarimetry.

American chemists, on their side, have created an industry of pure organic products in order to be independent of Germany. The Pfanstiehl Company, for example, specialises in bacteriological sugars, and the Kodak Company either produces or distributes gratuitously more than 750 organic compounds. All these efforts are co-ordinated by the National Research Council, and the work already accomplished is very remarkable.

Plans of the Belgian Chemical Society.—The above examples have instigated the Société chimique de Belgique to undertake similar work by providing a collection of pure standard substances, to be located partly in the University of Brussels. At the conference of the International Union of Pure and Applied Chemistry held in Rome (July, 1920), the Belgian delegates MM. Lucion and Swarts presented a memorandum by M. Crismer detailing the reasons for establishing such a collec-

* Translation, slightly abridged, of a paper presented by J. Timmermans to the Société Chimique de Belgique on January 30, 1921, and published in the Bulletin de la Société Chimique de Belgique, Vol. 30, 1921:

† The Reichsanstalt prescribes five grades of impurity, as follows:—Grade 1, containing from 1 to 10% of impurity; grade 2, from 0·1 to 1%; grade 3, from 0·01 to 0·1%; grade 4, from 0·001 to 0·01%; and grade 5, from 0·0001 to 0·001%.

tion. In response, the conference decided to establish a Bureau of Chemical Standards and to entrust its organisation to Belgium. Already before the war the author had started a collection of pure organic liquids, and thanks to the help of M. Chavanne had received a grant from the Solvay International Chemical Institute which enabled him to collect a number of organic products to serve as starting material for the preparation of standards.

The programme has been sketched out as follows:—

(1) It is proposed gradually to extend the existing collection until it contains samples of every well-defined chemical product, but in the first place efforts will be concentrated on, although not confined to, the collection of pure organic liquids, substances which are particularly difficult to obtain at the present time. The collection should therefore contain representatives of typical organic substances which can be preserved in a state of purity without too much difficulty. For this reason it is not proposed to keep esters which are readily hydrolysed, but only the acids and alcohols from which they are derived.

(2) It is intended to maintain a depôt of standard substances which have been prepared in the United States, or in any country adhering to the International Union, so that the results of the labours of American chemists may be made available to their colleagues in Europe.

(3) Small quantities of the standard substances will be placed at the disposal of Belgian and foreign scientists to save them the tedious work of re-purification. It will therefore be desirable that the samples shall be made from single batches of materials weighing several kilograms; and this will inevitably lock up considerable capital.

(4) The Bureau will act as a centre of information on all matters appertaining to pure products, rare specimens, and the relevant literature.

How to help the Bureau.—(1) To-day more than ever money is the nerve of action, and therefore all who appreciate the importance of the work are asked to aid in developing its financial resources. Such an undertaking far exceeds the power of any one man, but a relatively small endowment would suffice for the institution of research scholarships to enable the Bureau to obtain the necessary collaborators.

(2) Industrial firms will be free to make a substance once the method of preparation has been definitely established. The Bureau, content with its *rôle* of pioneer, will then be able to turn its attention to new preparations. It is hoped that the example set by the Kodak Company in America will be followed in Europe. Manufacturers, in their turn, will be able to render great assistance by supplying the necessary starting materials and raw products, so reducing the amount of capital locked up in the collection; in this way they would encourage scientific work of general interest.

(3) In conclusion, directors of laboratories can greatly assist their colleagues by placing at the disposal of the Bureau specimens of pure materials or rare substances which they have made in the course of their work and which may be useful as standards. If a director wished to retain the material himself, he could make known to others, by means of the Bureau, that his specimens were available; and exchanges could be effected that would be advantageous to all concerned. For a similar reason specialists in this sphere are asked to keep the Bureau informed of the progress of their work, in order that it may be made known to all interested in the subject.

With the help of Belgian and foreign chemists it is hoped to carry out this programme of work; and for this the memory of Stas, that pioneer of chemical standards, will act as a stimulus.

TURPENTINE IN THE UNITED STATES.

A recent bulletin by F. P. Veitch and V. E. Grotlisch (U.S. Dept. Agric., Bureau of Chem. Bulletin No. 898. 1920) contains much useful information on the production, marketing, and uses of turpentine in America. About 75 per cent. of the world's supply of turpentine is produced in the United States, chiefly from the southern longleaf yellow pine (*Pinus palustris*), but other species, such as the Cuban or slash pine (*P. caribœa* or *heterophylla*), the rosemary pine (a variety of the loblolly pine *P. taeda*) and the western yellow pine (*P. ponderosa*) are also tapped; most of the remaining 25 per cent. is obtained in the south-western coast regions of France from the maritime or cluster pine (*P. pinaster* or *maritima*). The relative production of turpentine in the various States of America is approximately as follows:—Florida, 37 per cent.; Georgia, 19 per cent.; Louisiana, 15 per cent.; Alabama, 12 per cent.; Mississippi, 9 per cent.; Texas, 7 per cent.; North and South Carolina, less than 1 per cent. Formerly North Carolina produced the bulk of the world's supply of turpentine. At present less than 10 per cent. of the total is wood turpentine obtained from stumps and deal or fallen timber by steam or destructive distillation; this source of turpentine is becoming more important.

The oleo-resin is obtained by scarifying or "chipping" the living trees. A V-shaped cut is made about once a week immediately above the last cut, thereby forming a "face," down which the gum exuding from the cut flows and collects in galvanised iron or baked clay cups holding 1 to 2 quarts. The tapping season lasts from early spring to late autumn, the oleo-resin being removed from the cups about once a month and taken to the still in barrels.

The distillation plant is simple and has not been improved materially during the last 50 to 60 years; it consists of a copper still of 500 to 1000 gallons capacity, with a still-head (generally removable) connected to a large copper condensing-coil cooled in water. From 7 to 14 barrels of oleo-resin go to make a charge, depending on the size of the still and the nature of the oleo-resin.

The oleo-resin contains some water, and the distillate at the commencement consists of about 45 per cent. of turpentine and 55 per cent. of water. When most of the water originally present has passed over, as shown by a decrease of the water contained in the distillate to about 30 per cent., and by the peculiar sound which is heard close to the tail-pipe of the condenser coil, a small stream of water is admitted to the still. The distillate is collected in a barrel in which it separates from water; it is desirable to cover the barrel to avoid loss by evaporation. The yield of turpentine varies from 16 to 22 per cent. The turpentine is mostly shipped in wooden casks holding 50 to 53 U.S. gallons (231 cb. in.). These barrels are treated internally with two coats of glue to prevent the turpentine from penetrating the wood; steel drums are used only to a slight extent, but the larger producers, especially in the more western States, employ tank-cars of 5 to 10 thousand gallons capacity. On arrival at the primary markets each barrel or tank-car is inspected, and the grade (colour), purity and freedom from water, and volume of the turpentine determined.

The total production in the U.S.A. for the 1919 season amounted to 366,000 casks (50 galls.) of turpentine and 1,237,000 barrels (500 lb.) of rosin; during 1920 up to August 1, 237,155 casks of turpentine and 712,387 barrels of rosin were produced, the estimated production for the rest of the season being

233,876 casks of turpentine and 739,679 barrels of rosin.

The bulletin gives details of the market customs prevailing in the U.S. turpentine trade, of the methods employed in gauging barrels and tank-cars, together with references to the laws governing the sale of turpentine in various States, and also quotes the specifications recommended for turpentine by the U.S. Inter-departmental Committee on Paint Specification Standardisation (Oct., 1919), with full details of the methods of sampling and analysis.

SOCIETY OF CHEMICAL INDUSTRY.

ANNUAL MEETING, 1921.

Accommodation on the s.s. "Melita."

Members and their friends who intend proceeding to Canada for the meeting, and who have decided to travel with the President and his party on the "Melita" (not the "Megantic," as inadvertently stated in the last issue), are requested to secure their berths with the least possible delay. The offices of the C.P.O.S. are: Pierhead, Liverpool; 62-65, Charing Cross, Trafalgar Square, S.W. 1; and 103, Leadenhall Street, E.C. 3; at any one of which arrangements may be made.

Return Sailings from Montreal.

For the information of those who desire to return *viâ* Montreal, the following sailings of C.P.O.S. steamers are given:—

	First Class Minimum £ s.	Second Class Minimum £ s.
Sept. 10. Empress of Britain	51 10	31 10
Sept. 16. Victorian	—	30 0
Sept. 20. Metagama	—	32 10
Sept. 23. Melita	—	32 10
Sept. 24. Empress of France	51 10	31 10
Sept. 30. Minnedosa	—	32 10

"Empress" steamers sail from Quebec only, but free railway tickets will be provided between Montreal and Quebec. All other steamers carry "cabin" class only from Montreal. Members and their friends who wish to return home by one of these boats should communicate with the C.P.O.S. before the end of June, and the company will arrange for reserved accommodation.

Passport Regulations.

The following information regarding passport regulations should be noted: Passengers travelling to the United States *viâ* Canada and passengers proceeding to Canada *viâ* the United States must obtain the U.S. consular *visa* on their passports before they leave the United Kingdom. Passengers who are not U.S. citizens must make *personal application* for *visa* at the U.S. Consulate nearest their place of residence. One photograph of each passenger is required. Application should be made not less than two weeks prior to the date of sailing. Passengers travelling from the United Kingdom to the U.S. *viâ* Canada cannot obtain the American consular *visa* in Canada; it must be obtained in the United Kingdom prior to sailing. Forms and full information regarding procedure are obtainable at the Canadian Pacific offices.

U.S. Head Tax.—As required by the U.S. Government, all passengers (excepting U.S. citizens) proceeding to points in the United States must pay at the time of booking the head tax of £2 5s. per person in addition to the ocean fare; children under 16 years of age accompanying their father or their mother are exempt.

VISIT TO SHAWINIGAN.

Arrangements have been made to take the visiting members of the Society to Shawinigan Falls immediately after the conclusion of the Annual Meeting. A special train is being provided for members and their friends, which will leave Montreal at 11.30 p.m. and arrive at Shawinigan Falls next morning.

Shawinigan Falls owes its existence to the splendid electric-power development; prior to 1898 it was a forest wilderness, but the year following the Shawinigan Water and Power Co. installed two 5000 h.p. generators, which formed the nucleus of the present development of the district, now amounting to over 300,000 h.-p. It is estimated that the district has a potential capacity of over a million h.-p.; this power is the foundation of a group of chemical industries which compare favourably with any on the American continent using over 130,000 h.-p.

The pioneer chemical industry to be established was the Northern Aluminum Co., which started operations about 1901 and now uses ten times as many h.-p. as at that time. The principal raw material—bauxite—has not yet been discovered in Canada, but is imported from Arkansas. The process followed is the well-known Hall method of producing aluminium by direct current, using a bath of alumina in fused cryolite. In addition to manufacturing aluminium, the company also maintains a wire-drawing plant, and makes all the aluminium wires and cables used in Canada.

Following closely on the heels of the Aluminum Company, the Belgo-Canadian Pulp and Paper Co. started operations in 1903. This undertaking owns large timber areas on the St. Maurice River and its branches, down the streams of which the logs are floated to the mill. The company produces both ground-wood and chemical pulp, and in addition makes over 90 tons of paper per day.

The Canada Carbide Co. was established in 1903, the first installation being one small single-phase electric furnace. From this small beginning it has grown to such an extent that it now occupies some fifteen acres of land, upon which have been erected lime-kilns, buildings for storage, two main rooms where the carbide is produced in furnaces ranging from 3000 to 10,000 h.-p. The carbide is crushed, sorted and packed in separate rooms, and there is a small plant for manufacturing steel drums and wooden crates for shipping.

The Canadian Electro-Products Co. came into existence to supply the demand for acetone in cordite manufacture during the war. Production from calcium acetate obtained by wood distillation proved entirely inadequate and, at the request of the British Ministry of Munitions, the Shawinigan company started investigating the possibility of producing acetone synthetically from acetylene. The experimental work was begun in December, 1915, and after a half-year's intensive research by five Canadian chemists, construction was commenced in May, 1916. By January, 1917, the whole plant, covering fifteen acres, was complete, and the first car of acetone shipped to England. The working out of the process, of which the steps are carbide→acetylene→acetaldehyde→acetic acid→acetone, involved the development on a large scale of reactions hitherto only performed in the laboratory and which presented difficult and unusual problems; and it is very much to the credit of those concerned that when the plant was doubled at the entry of the United States into the war only a few minor changes were made in the design and arrangement of the equipment. The production exceeded 10,000 tons of acetic acid in 1918. Acetone is not manufactured at the present time; the process is stopped at the acetic-acid stage, 99 per cent. acetic acid being obtained in one distillation.

Plans are now being made to produce acetic anhydride, monochloracetic acid, aspirin, etc.

The Canadian Aloxite Co., a subsidiary of the Carborundum Co. of America, started about two years ago and is gradually increasing its operations, so that in the near future it will utilise 20,000 h.-p. The products are ferro-silicon and abrasives.

The demand for electrodes for the electric furnaces at Shawinigan Falls and Montreal led to the formation of the Canadian Electrode Co., which has a plant capable of meeting all the requirements of the locality. Only carbon electrodes are now made.

Rarely can one find in so restricted an area so many industries of which the life depends upon chemical research.

MEETING OF LEATHER CHEMISTS IN NEW YORK.

A letter has been received from Mr. J. A. Wilson, chairman of the Leather Chemistry Section of the American Chemical Society, extending a very cordial invitation to the leather chemists of this country to attend the sectional meetings in New York City during the week beginning September 5, 1921. It is anticipated that some very important papers will be read which will mark the beginning of a new and vigorous development of the chemistry and microscopy of leather manufacture. Papers in course of preparation relate to the microscopy of hide and leather at all stages of the process, the action of enzymes in bating, the chemistry of the tannins, chrome and vegetable tanning, and vegetable tannin analysis. British chemists are invited to contribute papers, and if they cannot attend the meeting they are asked to send them to Mr. Wilson (203, Juneau Avenue, New York) to reach him not later than August 6.

NEWS FROM THE SECTIONS.

NEWCASTLE.

A dinner was given by members of the Section on April 23, in the Central Station Hotel, in honour of the President of the Society. Dr. J. H. Paterson presided, and among those present were the Rt. Hon. the Lord Mayor of Newcastle, Mr. A. E. Doxford (chairman, N.E. Coast Institution of Engineers and Shipbuilders), Mr. G. Vardy (president, British Foundrymens' Association), Dr. J. P. Longstaff, Professors P. P. Bedson, Henry Louis and W. N. Haworth, Dr. J. T. Dunn, and Mr. E. Morley Fletcher.

Dr. Paterson, in proposing the toast of the Society, coupled with the name of the President, said that they were all proud of the Society, which was one of the most influential societies in the country, if not the largest numerically. They were proud of the Society's *Journal*, which was one of the most advanced and best-arranged journals in the world, and they were also proud of their President, whose work was known and appreciated far beyond the ranks of their own members. Sir William Pope said that he was fully confident that the future of the Society would be as glorious as its past. The criticisms that were occasionally heard really demonstrated that the Society was alive, and that progress was being made. He agreed with the chairman that the *Journal* was one of the foremost in the world. After alluding to the great part which the Newcastle Section had played in the success of the Society, and to its distinguished past-presidents, Sir William Pope spoke of the forthcoming annual meeting in Canada, and appealed to the Section, and to all the other Sections, to send as many members as possible to take part in it.

Prof. P. Phillips Bedson proposed the health of the Lord Mayor of Newcastle, Prof. H. Louis that of the guests, Dr. J. P. Longstaff that of Armstrong College, and Dr. F. C. Garrett that of the hon. local secretary and hon. treasurer. The chairman gave the health of Prof. Bedson, who has been a tower of strength to the Newcastle Section, and who is shortly to retire from the chair of chemistry at Armstrong College, after nearly 40 years' service.

At the annual meeting which preceded the dinner, the officers of the Section were re-elected, and the following were elected members of the committee, out of 18 nominations:—Messrs. P. E. Bowles, W. Diamond, J. T. Dunn, F. C. Garrett, F. Hirsch, D. W. Jones, H. Louis, H. Peile, A. Short, F. H. Walker, and G. Weyman.

BIRMINGHAM.

The annual meeting was held in the University buildings on April 14, Dr. H. W. Brownsdon presiding. There are no changes to report in the list of officers of the Section, but the following were elected to fill vacancies on the committee:—Messrs. W. Brazier, G. H. Blenkarn, F. L. W. Bradford, H. T. Pinnock, and W. C. Davis.

Dr. E. B. Maxted read a paper on "The Manufacture of Pure Hydrogen and the Catalytic Hydrogenation of Oils." In discussing the four methods by which hydrogen is now usually prepared for use in industrial catalytic processes, the author stated that the electrolytic and the cyclic water-gas processes gave sufficiently pure hydrogen for direct use, but the gas obtained by the low-temperature separation of the constituents of water gas and by the catalytic water-gas process required to be further purified from carbon monoxide. The cyclic water-gas method was particularly suitable for manufacturing hydrogen for the hardening of oils. Dr. Maxted then explained the origin of the small amount of carbon monoxide occurring in the hydrogen produced in the last-mentioned process, and pointed out that the deposition of carbon, which was the *bête noire* of this process, could be easily prevented by varying the composition of the gas used for reduction, viz., by using in place of ordinary water gas a gas somewhat richer in carbon dioxide, such as was obtained with a water-gas producer constructed for operating at an abnormally low temperature. In the hydrogenation of oils, it appeared that traces of oxygen or nitrogen acted principally as diluents, but in certain other catalytic reactions, traces of oxygen acted as an inhibitant, and it was then necessary to use water for generating the steam which was as free as possible from dissolved air. The *modus operandi* of hydrogenation was then outlined, and this was followed by remarks upon the nature and activity of the nickel catalyst, the influence of temperature and speed of reaction. In the hydrogenation of ordinary commercial oils, it was the author's practice to begin hardening at 120°—130° C. and to allow the temperature to rise to a maximum of about 160° C.

GLASGOW.

A paper on "Tar Distillation" was read by Mr. W. A. Walmsley, of the Glasgow Corporation Chemical Works, at a meeting held on March 22, Mr. J. H. Young presiding.

Crude tar is difficult to distil when any ammonia water remains in it; an actual charge of 30 tons in a pot still requires 22 hours for the removal of water and crude naphtha, and only 6 hours further to complete the distillation to pitch. Modern stills are designed to obviate this long period of distillation of water and naphtha, and at the same time to economise fuel. The vapours from the stills are passed through coils covered by crude tar in a

pre-heater, whereby they are cooled and the crude tar is dehydrated. A further development of this principle is found in the continuous tar-distillation plant. Incoming tar is gradually warmed by meeting outgoing vapours, and in passing through a series of stills is stripped of fraction after fraction until pitch only is left. The system is not elastic enough in its present form.

Dehydration by pumping crude tar through heated coils and releasing suddenly to atmospheric pressure is being successfully accomplished, and the same system is used in working up crude oils to recover naphtha, this product being liberated on expansion.

The manufacture of caustic soda for phenol recovery is an essential process, and for its preparation on a large scale a continuous system is adopted. The settling of precipitated calcium carbonate is accelerated by gently moving paddles, and the sludge is continuously dried on a revolving filter ready for recalcination, if this is commercially justifiable. Little power is used in mixing the oils with caustic soda solution when the agitation is done by creating a vortex and breaking the surface by shallow baffles.

In rectifying naphthas, a very good column is one in which the vapours travel in a downward direction in each section and are subjected to the scrubbing action of descending condensate.

The entire works and individual plants should be designed to provide a continuous flow of products in one direction, effluents also tending in one direction.

The above processes are in operation or are being installed in the Chemical Works Department of the Glasgow Corporation.

LIVERPOOL.

The annual meeting of the Section was held on April 29 at the Adelphi Hotel, Liverpool, Dr. E. F. Armstrong presiding. Dr. G. C. Clayton, of the United Alkali Co., was elected chairman, in succession to Dr. Armstrong, who now becomes vice-chairman. After many years' good service, Dr. A. Holt retires from the hon. secretaryship in favour of Mr. E. Gabriel Jones, but remains on the committee as hon. treasurer, Mr. Edwin Thompson becoming the Sectional representative on the Chemical Engineering Group. The following were elected to the committee in place of retiring members:—Messrs. C. O. Bannister, G. W. Beaumont, A. E. Findley, E. L. Peck, and Edwin Thompson.

After the business meeting, a paper on "Mustard Gas" was read by the President, Sir William Pope.

YORKSHIRE.

Mr. S. H. Davies presided at the annual meeting of the Section held at Leeds on May 2. The officers were re-elected, and as five members of the committee retired and one member had resigned, the following were elected to fill the vacancies:—Messrs. C. P. Finn, W. B. Hill, H. J. Hodsman, P. E. King, F. W. Richardson, and B. Watmough. The chairman said that unfortunately there had been few papers read during the past session, but it was hoped to have more next year, and it was proposed to hold meetings in centres other than Leeds, such as Sheffield, Huddersfield, or Bradford.

Prof. A. Smithells then gave a demonstration, with models, of modern views of the chemical atom, his aim being to set his audience re-studying the broad fundamentals of the subject, especially Dr. Irving Langmuir's paper on the arrangement of the electrons in the atom. The advance of chemical theory since Dalton's time was sketched, the conceptions of Dalton, Berzelius, and Van't Hoff being illustrated by models representing washing soda. Study of radio-active disintegration pointed to the necessity of going beyond the atom and of postulating its complexity and an electrical theory of matter. The existence of the electron is now questioned by no one. The lecturer referred to the isolation of the negative electron and the association of mass with the positive electron, the Bohr hydrogen atom, and the Rutherford atom. Before describing the Langmuir atom, the postulate was put forward that in order to be of service to the chemist it must explain the chemical properties of the elements as expressed, say, in the periodic classification of the elements, and their stability chemically and physically must be in accordance with the theory. The Langmuir atom was then illustrated by models and its accordance with the properties of the elements of the helium series was brought out. Langmuir's view of the combination of the elements was demonstrated, and a model showing the structure of the sodium carbonate molecule was built up from models of the constituent atoms. Other interesting models dealt with the methane molecule, the similarity of the nitrogen and carbon monoxide models from the point of view of their inactivity, and the atom of nickel.

LONDON.

The annual meeting was held on May 2, at Burlington House, W. Mr. Julian L. Baker, the chairman, in the course of an address, announced that Mr. E. V. Evans was to succeed him in the chair, and that Dr. Monier-Williams had been re-elected hon. local secretary. At the six meetings of the Section which had been held so far eight papers had been read, and the average attendance had been 97 members and 21 visitors. The committee had had under consideration the question of holding joint meetings with the Chemical Engineering Group, and it was hoped that it would be possible to arrange occasional joint meetings of the Société de Chimie Industrielle and either the parent Society or the London Section. He appealed to members to make every effort to attend the Annual Meeting in Canada, and he also drew attention to the informal dinners of the Section which were held before the meetings, and at which a better attendance was desirable.

The following were elected to fill vacancies on the committee:—Messrs. R. T. Colgate, H. G. Colman, H. F. E. Hulton, S. Miall, H. P. Stevens, and E. W. Voelcker.

The following papers were then read:—(1) "Fractional Distillation with Contract-ring Still-heads," by Dr. R. Lessing; and (2) "Thermal Losses in the Gas Producer Process," by Mr. N. E. Rambush.

(1) Dr. Lessing's contact-rings consist of metal cylinders of approximately equal height and diameter, provided with a narrow slit from end to end and a diametrical partition connected to one side of the slit. They are dropped promiscuously into a cylindrical still-head, and owing to the large amount of free space remaining, about 87 per cent., the resistance in the still-head is almost negligible. The author's experiments have shown that the efficiency of these heads is greater than that of any other dephlegmator, and is due to the large surface per unit of volume, the turbulence caused by frequent deflection of currents of vapours and condensate, and the consequent absence of channelling. Maximum efficiency may be obtained by lagging or heating the still-head and by super-imposing a reflux condenser. The rings, which are made of copper or aluminium, are used in scrubbing-towers, condensers, heat-exchangers, etc., especially when a minimum of back pressure is essential; for such purposes the size recommended is 1×1 in., but smaller sizes are available for laboratory use.

(2) Mr. Rambush's paper described the results of an exhaustive research on the cause of the heat-losses in the gas-producer process. The factors concerned in the losses are:—(*a*) The moisture-content of the fuel, which is roughly proportional to the thermal loss; (*b*) the amount of condensable volatile matter obtained by gasifying the fuel; (*c*) the loss of dust and soot due to high gas velocities and high temperatures, which may lead to a loss of 3 per cent. in the heating value of the fuel; (*d*) the ash content of the fuel—the higher the ash content the greater the amount of unburnt carbon; (*e*) radiation and convection, which cause a loss of about 1 per cent. in the heating value of the fuel gasified; (*f*) leakage due to poking, cleaning, and bad joints, which may amount to a loss of at least 1 per cent. of the heating value; (*g*) the mechanical removal of gas and the solution of gas and tar in the cleaning plant may cause a loss of 1 per cent.; (*h*) the water-vapour content of the gas derived from the undecomposed blast steam, the amount of which depends upon the time factor; (*i*) the heat carried away in the hot gases from the producer causes the highest thermal loss in cold gas producers, but is negligible in the case of hot-gas plant. When using fuel unevenly graded or in large pieces the fuel depth must be greater to ensure efficient gasification. The heat loss in the hot ashes is negligible, ranging from 0·1 to 0·5 per cent.

The author described his method of calculating the thermal efficiency of a producer plant, and his results were in good agreement with those obtained in actual practice. The relative losses obtained in various forms of plant when using an average English coal were found to be:—Hot gas producer (if cooled), 17 per cent.; cold gas producer (without recovery), 14 per cent.; and the ordinary Mond type of by-product producer, 16 per cent.

MEETINGS OF OTHER SOCIETIES.

THE ROYAL INSTITUTION.

The Friday Evening Discourse on April 22 was delivered by Sir James Walker on "The Electro-synthesis of Organic Compounds." The ionic theory of electrolytic conduction was briefly reviewed, and incidentally it was pointed out that electrolytic vessels now used are still very similar in form to those employed by Faraday, whose studies were confined entirely to the electrolysis of solutions of inorganic substances. In preparing ethane by the electrolysis of an aqueous solution of sodium acetate in 1849, Kilbe established his right to be regarded as the pioneer of the electro-synthesis of organic substances. In 1890 Crum Brown attempted to extend Kolbe's method by electrolysing sodium ethyl tartrate, but without result. The lecturer had then pursued the subject by attempting the electrolysis of sodium ethyl malonate. The result indicated a general method for the electro-synthesis of organic substances which may be represented by the equation:—

$$\left.\begin{array}{l} NaOOC.X.COOC_2H_5 \rightarrow \overset{+}{Na} + \boxed{CO_2} \\ NaOOC.X.COOC_2H_5 \rightarrow \overset{+}{Na} + \boxed{CO_2} \end{array}\right| + C_2H_5.OOC.X_2.COO.C_2H_5$$

where X represents any organic group. The C_2H_5-group in the resulting synthetic product may be substituted by sodium and the synthesis carried a step further, whereby a product containing four X-groups is obtained. The method can be applied to the electrolysis of mixtures, thus enabling compounds to be synthesised which contain groups X in the order of their natural number. In the particular case where X represents the CH_2-group, the electrolysis of sodium ethyl malonate results in the production of diethyl succinate. In this manner the lecturer had succeeded in synthesising from malonic acid, substances containing up to 16 CH_2-groups. Substances containing 32 CH_2-groups had not hitherto been synthesised in this manner—probably owing to electrolytic difficulties connected with the fact that these synthesised products were of the nature of soaps. The method had not hitherto been applied with success to the electro-synthesis of aromatic substances, but investigations were now being made. Generally speaking, investigation of the electro-synthesis of organic compounds had been much neglected in recent years.

THE OPTICAL SOCIETY.

At a meeting held on April 14, Mr. F. Twyman, of Messrs. Adam Hilger, Ltd., described "An Interferometer for Testing Camera Lenses," which is an application to camera-lens testing of the principles of an earlier instrument described in the Philosophical Magazine (Phil. Mag., 35, Jan., 1918), but it differs from the lens interferometer there described in that the camera lenses can be tested for oblique pencils. The instrument gives aberrations in the form of an interference picture (that can be photographed), which is a contour map of the aberrations of wave-front expressed in wave-lengths of light in comparison with the wave-front of a perfect camera lens.

A paper on "The Testing of Heliograph Mirrors and the Measurement of Mirrors of Long Focal Lengths" was read by Mr. W. Shackleton. The method of testing the general surface consists in observing the reflection from the mirror of a system of squares on the test board, the magnification given by the mirror being utilised to determine the curvature. The method of examination is applicable to the rapid measurement of mirrors of long focal length, especially of those forms silvered on the back, cata-dioptric mirrors, where the usual methods of measurement, test planes or spherometers, are inapplicable. Defects of curvature and distortion, astigmatism, and striæ in the glass can be detected, and also defects of silvering and bad polishing.

THE INSTITUTE OF PHYSICS.

The inaugural meeting of this new professional body was held in the hall of the Institution of Civil Engineers on April 27. Sir Richard Glazebrook, who presided, urged the claims of physics in national life, and said that its utility during the late war had done much to impress the nation with its essential importance. There were already about 300 members in the Institute, including most of the leaders in physical science.

Sir J. J. Thomson, the president-designate, compared the conditions to-day with those of 50 years ago. Then there were probably not more than about 100 physicists and a dozen small physical laboratories in the country; the only posts open to physicists were badly-paid professorships and worse-paid school appointments. The number of laboratories had very greatly increased, but the supply of physicists, although it had also increased, was far below the demand. There was a great need of physicists in industry, not only in the laboratories but in the works themselves. Science students at the Universities should spend at least one year on research, if only on account of the mental discipline it afforded. "Research develops character, increases independence of thought, and develops resourcefulness, critical power, and enthusiasm; in fact, it raises the student from intellectual ado-

lescence to intellectual manhood." The growth of physical research was illustrated by the increased number of original papers published; he estimated that there were about 2700 such papers in 1913, as against 400 in 1873. Although pioneer work was of the first importance, routine work was nevertheless essential.

The Rt. Hon. A. J. Balfour claimed that physics was the most fundamental of all the sciences, and said it was surprising that this country had had to wait until 1921 for the foundation of an Institute of Physics. He was doing his best to help on the admirable work of the Department of Scientific and Industrial Research, about which the public knew so little; but the public seldom knew much about what concerned it most. If half the time and half the money now being spent on petty squabbles about the division of the products of industry were devoted to increasing the power of man over Nature, there would be much more of those products to divide among the community. Expenditure of money and energy and the mere multiplication of students would not increase the number of great discoverers; but organisation and money were needed for that routine work which was absolutely essential to the promotion of great discoveries and to bring them to fruition. No money was better spent than on scientific research, and he was often surprised that the imagination of great magnates was not stimulated by the thought that by encouraging research they could effectively add to the wealth of the whole world. A fruitful discovery not only benefited the company, or capitalist, but it often touched the lives of every dweller in every civilised country, and no one could truthfully say that that was a low, material view of things. The idea of progress which held out most hope for the future was that the growth of science and invention would bring comfort and leisure—to those who knew how to use it—where at present discomfort and labour were the necessary conditions of production.

THE TEXTILE INSTITUTE.

The report presented to the annual meeting held in Manchester on April 27 refers to the loss by death during the year of Sir William Mather and of the president, Sir A. Herbert Dixon. The Foundation Fund, by means of which the Council hopes to embark on a definite programme of work, is as yet far short of the £50,000 required; nevertheless the annual income from the sum already raised has permitted an extension of activities which would otherwise have been impossible. The Compton Prize Scheme competition for advanced students is working successfully; the *Journal* has undergone important developments, and the institution of the annual "Mather" Lecture has proved of distinct value. There has been a substantial increase in membership, which now numbers 915.

In moving the adoption of the report the president, Colonel F. R. McConnel, made a number of suggestions for extending the scope and influence of the Institute, and said it was hoped that the committee charged with the work would soon complete the plans for a system of fellowships. The Institute, he said, was doing excellent service in showing how all ranks in industry could cooperate in attacking technical and scientific problems, and to that extent was influencing for good the relations between employer and employed.

After the business meeting Mr. W. E. Baker read a paper on "Ball and Roller Bearings as applied to Spinning, Weaving, and Finishing Machinery," which, from the chemical standpoint, was of interest, as it drew attention to the extreme cleanliness obtained by means of ball-bearings; at the present time large quantities of valuable material—yarn, cloth, and liquors—are spoiled by the dirtiness of plain bearings and the drip and throwing of dirty oil from them.

SOCIETY OF PUBLIC ANALYSTS.

At the meeting held on May 4, Mr. A. Smetham in the chair, Messrs. F. G. H. Tate and J. W. Pooley contributed a paper on "Detection and Estimation of Illipe Nut Fat used as a Substitute for Cocoa Butter," in which they described a method of calculating the percentage composition of any mixture of these two fats from the densities, the melting-points of the fat and fatty acids, the viscosity and the iodine value. Dr. G. W. Monier Williams demonstrated an inexpensive apparatus for determining hydrogen-ion concentration, and discussed the underlying theory and its application to analytical work. In "A Note on the Oil of Oats," Mr. E. Paul described some work on the extraction with petroleum ether of whole-ground oats of the "Black Tartary" variety. Lecithins were found in the extract, and the constants of the separated oil were determined. The last paper was by Mr. H. Atkinson on the "Estimation of Potassium in presence of Sodium, Magnesium, Sulphates and Phosphates." The method described is based upon the relatively low solubility of potassium perchlorate in methyl alcohol compared with the solubilities of the perchlorates, sulphates, and phosphates of magnesium and sodium.

THE CHEMICAL SOCIETY.

Four papers were read at the meeting held on March 5, Dr. M. O. Forster presiding. "Amylases of the Cereal Grains: Rye" was presented by Mr. Julian L. Baker and Mr. H. F. E. Hulton, who have found that when ungerminated rye diastase acts upon starch paste or soluble starch at 50° C., crystallisable maltose and α-amylodextrin only are formed. Rye diastase, however, is superior to barley in its capacity to liquefy starch paste, and it also gives a somewhat higher yield of maltose. The diastase of germinated (malted) rye gives from 76—86 per cent. of readily crystallisable maltose and a reducing dextrin having $[\alpha]_D = +184$ and a reducing power of 10 (calculated as maltose). No intermediate products degradable by the further action of diastase (malto-dextrins) were obtained as when barley malt diastase acts upon starch paste under similar conditions.

In a paper on the "Hydrolysis of Cotton Cellulose," Dr. G. W. Monier-Williams described how he had converted cotton cellulose almost quantitatively into crystalline dextrose by direct hydrolysis. Ten grams of cotton wool were dissolved in 50 c.c. of 72 per cent. sulphuric acid and the viscous solution allowed to stand for one week. It was then diluted to 5 litres with water and the solution boiled for 15 hrs. After removal of the sulphuric acid with barium carbonate, the filtrate was evaporated to dryness under reduced pressure, being kept neutral to methyl red during the evaporation by repeated addition of sulphuric acid in small quantities. The sugar was extracted by methyl alcohol from the dry residue, and the methyl alcohol solution, after decolorisation with animal charcoal, slowly evaporated in a current of dry air. The residue was crystalline and contained 94·6 per cent. of dextrose, 3·3 per cent. of moisture, and 1·5 per cent. of ash. Calculated on the dry, ash-free cellulose, the yield of glucose amounted to 90·6 per cent. of the theoretical quantity.

The two other papers presented were:—"The Formation and Stability of Spiro-compounds. Pt. IV. The formation of ketones derived from open-chain and cyclic glutaric acids by the thermal decomposition of their calcium salts": G. A. R.

Kon; and "The Conditions underlying the Formation of Unsaturated and Cyclic Compounds from Halogenated Open-chain Derivatives. Pt. II. Products derived from α-halogenated adipic acids": C. K. Ingold.

SOCIETY OF GLASS TECHNOLOGY.

The fourth annual general meeting was held at University College, London, on April 20, 1921. The report stated that the total members on the roll at the end of 1920 was 620, 128 members having been elected during the year. There was a small deficit on the year's working, due to the increased cost of printing the Society's Journal. After the election of officers, the new president, Dr. M. W. Travers, delivered his presidential address on "The Importance of Quantitative Investigation in dealing with Technical Problems in the Glass Industry."

Lord Moulton, who was to have presided at the dinner that evening, had insisted upon the observance of the principle that industrial processes must be based upon quantitative investigation, with the result that whenever his Department took over a factory it was almost invariably found possible to increase the efficiency of the processes carried out in it. Efficiency resulted from the economic use of money or credit, labour, materials, and energy, and was only possible when the losses under each heading could be accurately ascertained. The energy balance-sheet was really as important as the financial balance-sheet, and each should be drawn out with equal care. Just as it was impossible to check waste of money if one merely kept account of gross receipts and expenditure, so it was equally impossible to check waste of energy if one knew only the total fuel consumption in a furnace. Each furnace should be studied with a view to ascertaining whether unnecessary losses could be checked, the fuel consumption reduced, and the efficiency increased. The investigation of the nature of gas-producer tar, its composition, heat of formation, and its influence on the efficiency of heat exchange in the furnace should be investigated; also the actual temperatures of the gases as they entered and left furnaces. Furnace design should be based upon quantitative knowledge of the laws of the flow of gases through channels and spaces. The outlet flues from a pot furnace were not made small in order *to keep the heat in the furnace*, but because the velocity of the gas through a flue of small section was necessarily high, and when the velocity of the outflow was high, comparatively large fluctuations in the pressure in the furnace induced relatively small changes in the rate of outflow.

A paper on "Automatic Glass-feeding Devices," by Messrs. G. Dowse and E. Meigh, was read by the latter.

The third annual dinner of the Society was held on April 20 at the Hotel Cecil. Dr. M. W. Travers presided, and the guests included Mr. A. Chaston Chapman, Prof. F. J. Cheshire, Mr. Dennis Herbert, M.P., Mr. W. Ide, Master of the Glass Sellers' Company, and Mr. R. S. Whipple, president of the Optical Society. Replying to the toast of "The Society of Glass Technology," proposed by Mr. A. Chaston Chapman, Dr. Travers referred to the proposed legislation for the protection of the scientific branch of the industry. The view that the tariffs suggested were unsuitable and inadequate was held not only by the manufacturers, but also by the scientific and industrial worlds dependent upon supplies of chemical glassware. The only assistance which would enable this branch of the industry to continue was the total prohibition of all chemical glassware except under licence. It was a matter of great regret that electric-lamp bulbs had not been provided for in the Bill.

NEWS AND NOTES.

SOUTH AFRICA.

The Fertiliser Industry.—According to a statement made by Major C. C. Frye, of the Cape Explosives Works, Ltd., his company is about to extend greatly the manufacture of fertilisers and hopes within a few months to supply the whole of the fertiliser requirements of the Union, which are said to be approximately 100,000 tons per annum. The cost of the buildings and plant (which are now in course of erection) will not fall far short of £250,000. Every kind of fertiliser is to be sold by the company. —(*S. Afr. J. Ind., Mar.*, 1921.)

AUSTRALIA.

Starch Production from the Zamia Palm in New South Wales.—As a result of investigations carried out by the Institute of Science and Industry, the Austral Starch Co. has been formed to produce starch from the Zamia palm. A factory has been erected on the south coast of New South Wales, and is about to commence operations. The company has been granted a licence to obtain Zamia bulbs from an area of 31,000 acres in the vicinity of Currawan, on condition that not less than 50 tons of dry starch shall be produced half-yearly.—(*Ind. Austral., Feb.* 24, 1921.)

Conservation of Wheat in South Australia.—During the war the conservation of the South Australian wheat crop was placed under the control of a scientific committee of which Dr. W. A. Hargreaves, Director of the Department of Chemistry, S.A., was chairman. Two methods were used successfully:—(a) Treatment with Gas. The stacked grain was enclosed in sheds covered with "malthoid" made as airtight as possible. Then air, freed from oxygen by being passed through a furnace similar to a gas producer but designed to give carbon dioxide, was blown into the shed for three or four weeks to asphyxiate the insects. As many as 200,000 bags of grain have been treated at one time with success. (b) Heat Treatment. Dr. Hargreaves has modified the Poole and Steele machine, in which the wheat is passed through a hot zone at 140°—150° F.: this method was put into practice in 1918, and large quantities of wheat have been successfully treated by it.

CANADA.

Mining in British Columbia.—On account of the continued low price of copper, the Granby Consolidated Mining, Smelting and Power Co. has reduced the wages of its employees, but the output of over 116 tons a month is still maintained. The Consolidated Mining and Smelting Co. is maintaining its zinc output with ore from the Sullivan mine, and its output of gold and copper has been increased. Now that the British American Nickel Corporation has closed its plant at Nickelton and the refinery at Deschenes, Que., the copper refinery of the Consolidated Co. is the only one at present operating in Canada. The concentrating plant of the Britannia Mining and Smelting Co., which was closed on November 30, 1920, owing to the low price of copper, has recently been destroyed by fire. With a daily capacity of 2500 t. of ore, the plant crushed 650,900 t. of ore during the first eleven months of 1920, and produced concentrates that yielded 8036 t. of copper. Practically none of the lead mines in the Slocan camp, the chief silver-lead mining area in British Columbia, is producing, but development work is proceeding at the Silversmith and a few other mines. A large belt of zinc-lead sulphides, 40 ft. wide and 3500 ft. long, has been uncovered at Bellevue, on the Illiance River, Alice Arm district, where some of the small veins contain up to 150 oz. of silver and \$2·20 in gold per ton.

The iron and coal deposits of the Copper River district have been examined on behalf of British interests, and if the properties are acquired blast furnaces will be erected near Port Edward, and the Provincial Government will pay bounties of \$3 per ton of iron produced from domestic ores, and \$1·50 per ton of iron produced from foreign ores.—(*Canad. Chem. & Met., Apr.*, 1921.)

JAPAN.

The Dextrin Industry.—The manufacture of dextrin in Japan has been organised on a commercial scale only within the last three or four years. At present the cost of production is about \$5·53 per 100 lb., whereas the selling price on the Osaka and Kobe markets is roughly \$5·13 per 100 lb. for white and \$5·58 for yellow dextrin. Thus the manufacturers are not making a profit, and unless the cost of production is reduced by lowering wages and prices of raw materials the industry may not survive the present depression. There are three small factories situated in Osaka, Tokyo, and Kyushu, respectively, and the total output of the whole country is about 300 tons a month. Dextrin is mainly used in the textile industry, and the Japanese product is exported chiefly to Great Britain.—(*U.S. Com. Rep., Mar.* 15, 1921.)

The Dyestuffs Industry.—The decline in prices subsequent to the armistice brought about severe depression in the Japanese dye industry, but imports of German dyestuffs were limited in amount, and some manufacturers resumed work late in 1919, the output in Tokyo-fu for the first five months of 1920 reaching a value of 1,503,000 yen (£153,306). The economic crisis which set in in April again curtailed production. Dyestuffs manufacture in Tokyo-fu began with Kryogene Black and was gradually extended to include Kryogene Brown, basic, acid, direct, mordant, and other dyes. The production of Kryogene and other dyes is given below:—

	Kryogene dyes.		Other dyes.	
	Long tons.	£	Long tons.	£
1918	176·5	38,913	290·4	359,329
1919	226·8	13,933	140·6	169,199
1920 (to May)	486·7	53,917	72·6	99,474

It will be seen that there was a considerable improvement in the output of Kryogene dyes up to the end of May, 1920, and that the production of other dyes was greater than in 1919, although much below that of 1918.—(*Bd. of Trade J., Apr.* 21, 1921.)

BRITISH INDIA.

Mineral Production in 1919.—In his report for 1919, the Chief Inspector of Mines states that the output of coal was 21,759,727 tons, or 9·64 per cent. more than in 1918; nearly 70 per cent. of the production came from the Province of Bihar and Orissa. The coal used for coking amounted to 1,025,168 t., and 278,473 t. of hard and 308,565 t. of soft coke were made; the increased production of hard coke was chiefly due to the exceptional prosperity of the iron and steel industries. The output of coal per person employed was (a) below ground, 185 t., and (b) above and below ground, 114 t., compared with the average figures of 178 and 113, respectively, during the five preceding years. Owing to the cessation of the war demand, the accumulation of stocks, and the rise in exchange (factors which affected most minerals), the output of mica declined by 19·18 per cent. to 2084 t.; production was cut down and Government control of the mica industry terminated. Demand for manganese was on the whole worse than in 1918, and prices declined; the output was 1·16 per cent. higher at 420,184 t. The decline in the output of wolfram continued, and the output was 2905·4 t., a decrease of 19·5 per cent.; production remained normal during the first four months, but in May the purchase price dropped from 72 to 30s. per unit, and by the end of the year the number of producing mines had fallen from 84 to 39. The output of copper ore was 32,756 t., compared with 3619 t. in 1918; 980 t. of copper was produced by the Cape Copper Co., which completed its mill and smelter at the Rakha mines in the Singbhum district. There was a decrease of 43·81 per cent. in the output of gold (11,191 oz.), and a decrease of 3·37 per cent. in that of gems (158,577 carats), despite the demand at higher prices for rubies and sapphires. There were increases in the production of limestone, salt, slate, magnesite, bauxite, clay, tin, fullers' earth, samarskite, graphite, ochre, and molybdenite, and decreases in silver, iron ore, chromite, galena, steatite, barytes, apatite, and potash.—(*Ind. Tr. J., Mar.* 18, 1921.)

FRANCE.

Industrial Notes.—*Metallurgy.*—Despite the uncertainty regarding the final financial settlement with Germany, the demand for pig iron and rolled products appears to indicate that trade in metallurgical products is reviving, and the keenness of demand for several finished products is a sure sign that consumers' stocks are running short. The question of exportation is again becoming prominent and a scheme is being considered involving an understanding between various iron and steel companies, and reduced transport charges to encourage exportation. It is also proposed to sell coal and coke from the Saar and Rhineland districts at special prices to exporting firms. The "Basset" process for the production of iron and steel direct from the ore (*cf.* J., 1920, 304 R) is still attracting attention, but no definite statement can yet be made as the process is apparently still in the experimental stage. It is stated, however, that the cost of production is very low, so low in fact that were the cost to hold good in large-scale practice the process would revolutionise metallurgical production. Preliminary experiments are being carried out with 25-ton furnaces at Dennemont, near Mantes, and steel for rails has been produced. Three works with four furnaces, each of a capacity of 250 metric tons a day, are being erected in Normandy for a new company, "La Société des Aciéries Basset," which is working the process and whose activities may later be extended to Eastern France and even abroad.

An "Aluminium Week," to be held in Paris from May 21 to 29, is announced by the Société d'Encouragement pour l'Industrie Nationale. There will be an exhibition and a series of lectures to encourage the use of aluminium, magnesium, calcium, and sodium, and to promote new applications.

Liquid Fuel.—Pending a definitive arrangement, import licences will be required for liquid fuels as from May 1, 1921, and the following conditions will have to be complied with:—(*a*) The importer must purchase from the State a quantity equal to the amount imported; (*b*) a tax of 15 fr. per hectolitre will be levied to compensate the State for losses due to the depreciated value of its stocks; (*c*) 25 per cent. of the quantity of liquid fuel imported must be kept continously in stock; and (*d*) the consumer must benefit from the lower prices accepted by the State.

Chemical Industry.—As yet there is no sign of improvement in the French chemical market, and several foreign markets, particularly Greece and South America, have been closed to France by German competition. Many German chemical products, particularly pharmaceutical chemicals, are even now finding their way into France, but a higher protective tariff and a general *ad valorem* duty on German imports should remedy this state of affairs. It is felt, however, that the real solution

lies in developing the French chemical industry so that it may turn out first-class products at minimum cost. The Cie. Cellulose Française d'Alfa, formed to manufacture paper and pulp from Algerian alfa, is contemplating the purchase of the Government's explosives factory at Toulouse, which has been practically dormant since the armistice. It would take 3—4 months to adapt the machinery to the company's requirements. The raw material would be shipped from Algeria to Cette, brought by canal to Toulouse, where it would be stored, and then carried by rail to the factory as required. The initial production is estimated at 20 metric tons of pulp from 40 t. of alfa, and the treatment would require 30 t. of coal, 1·5 t. of hydrochloric acid, and 3 t. of caustic soda; plant is available locally for the production of chlorine and caustic soda. It is estimated that paper pulp could be produced to sell at about one-half of the current price.

Alsatian Potash Mines.—The proposal to entrust the development of the Alsatian potash mines to a single company has been rejected by the Government Commission which is examining the question, and it has been decided to hand over the mines to four companies, which will have a common sales organisation both for home and foreign markets.

Meeting of Civil Engineers in France.—The summer meeting of the Société des Ingénieurs Civils de France will be held in France from June 18—24 next. The first five days will be devoted to a tour in Eastern France, including the battlefields of Verdun and the factories of Lorraine, and the last two days will be spent in Paris. Full particulars of the programme may be obtained on application to the offices of the British Section at 45, Great Marlborough Street, London, W. 1.

The Perfume Industry in the Lyons District.—Of late years the manufacture of artificial and natural perfumes in the neighbourhood of Lyons has expanded considerably, largely owing to the favourable geographical position and to the interest shown by the University of Lyons in offering a special course in perfumery. The Far East, Madagascar, and North Africa are the main sources of the raw materials used, but large supplies of lavender, iris, roses, etc., are obtained locally. The oil of verbena is transformed into violet, artificial iris and synthetic lily of the valley, oil of camphor into heliotrope, aniseed into anethol and artificial hawthorne, clove oil into vanilla, Guiana rosewood into bergamot, Madagascar faham into coumarin, etc. Lavender oil is produced in the Lyons district to the value of 10 million francs per annum, which, it is claimed, is 90 per cent. of the world's output. More than 12,350 acres are laid down to lavender in the district, but the cultivation of other flowers has been temporarily supplanted to some extent by that of food products. Synthetic perfumes are also manufactured and many of the factories which produced organic chemicals during the war now make perfumes. Thus, the toluene of a local firm is used for producing jasmine, artificial rose, as well as benzoate of soda, and the firm of Junillon, at Valence, makes a speciality of the production of synthetic musk from xylene. At present the industry is suffering from the trade depression, stocks have accumulated, and the principal buyers—America, England, and Japan—are not placing orders—(*U.S. Com. Rep., Feb.* 28, 1921.)

UNITED STATES.

The Beet-Sugar Crop in 1920–21.—It is estimated that if weather conditions remain favourable the United States beet-sugar crop for 1920–21 will amount to 997,710 long tons, the largest crop ever produced in that country. Previous crops have been as follows:—1915–16, 780,550 t.; 1916–17, 732,700 t.; 1917–18, 683,000 t.; 1918–19, 674,900 t.; and 1919–20, 653,000 t. Compared with last year, an additional 333,710 t. of home-grown sugar will probably be available, and as the United States is a large importer (*cf.* J., 1920, 183 R), this decrease in requirements of foreign sugar may influence sugar prices in the world markets.—(*Ind. Tr. J., Apr.* 1, 1921.)

Gypsum in 1919.—The quantity of gypsum mined in the United States in 1919 was 2,420,163 short tons, an increase of 18 per cent. over the output in 1918. All the producing States except Oklahoma showed an increase in output, ranging from 11 to 43 per cent., and large increases in value were also recorded. The distribution of the production was as follows:—Uncalcined: For Portland cement, 470,267 short tons; agricultural gypsum, 39,978 t. Calcined: Plaster of Paris, wall plaster, Keene's cement, etc., 1,393,141 t.; for glass manufacture, 14,677 t.; as boards, tiles, blocks, etc., 188,202 t. There were 56 active mines, quarries, and pits in the United States and Alaska, and these supplied 54 domestic calcining plants; most of the mills are equipped with kettles, but the number of rotary kilns is increasing, there being eight in 1919. Rock gypsum was mined in 41 localities, gypsite in 14, and selenite crystals in one. The imports of gypsum, mainly from Nova Scotia and New Brunswick, increased to 172,000 t. of crude and 10,000 t. of ground or calcined gypsum. Exports of plaster or wall board were valued at $1,141,815, an increase of nearly 171 per cent. over 1918, England being the largest buyer (27 per cent.), followed by Japan, Canada, and Australia. The demand from South America continued to grow (*cf.* J., 1920, 76 R).—(*U.S. Geol. Surv., Dec.* 28, 1920.)

Salt, Bromine, and Calcium Chloride in 1919.—Owing to transport deficiencies and the cessation of war demand, the production and sale of salt in 1919 declined by 4·9 per cent. to 6,882,902 short tons. During the war output rose by 9·8 per cent. in 1915, 18·9 per cent. in 1916, and by 9·7 per cent. in 1917, the use of electrolytic chlorine in the manufacture of poison gases being mainly responsible for the increase. Fifteen States produced salt in 1919, the chief being Michigan, New York, and Ohio, and there were 102 operating plants in the whole country, the same number as in 1918. The production of rock salt was 1,642,057 short tons, mined by 21 firms in seven States, chiefly in New York and Kansas, and that of brine salt was 5,240,845 t., largely from Michigan and New York. Brine salt alone was produced in greater quantity than in 1918, and as it is usually sold to or produced by chemical works, the variations in its production may to some extent be regarded as an index of the state of the chemical industries. Imports of salt for curing meat and fish amounted to 62,821 short tons, and were obtained mainly from Spain, British West Indies, and England; in 1918 the import was 40,320 t., and the pre-war average 150,000 t. Exports totalled 119,416 t., the decrease of 13 per cent. being probably due to a return to normal conditions.

About 928 short tons of bromine, valued at $1,234,969, was produced from the usual source, viz., bittern left after extracting salt from brine. Notwithstanding the cessation of the war demand, the production increased by 7·5 per cent. compared with 1918; the total given includes bromine marketed as bromides and other bromine salts.

The production of calcium chloride from natural brines was 26,123 short tons, a decrease of 1·9 per cent. Michigan, Ohio, West Virginia, and California remained the chief producing States of this type of calcium chloride (that produced in the ammonia-soda process being excluded); it contains from 2 to 6 per cent. of magnesium as an impurity (*cf.* J., 1919, 28 R).—(*U.S. Geol. Surv., Mar.* 26, 1921.)

GENERAL.

Increased Capitalisation of the German Chemical Industry.—The reports of the largest German chemical companies, published last month, show that enormous increases of capital are contemplated. The capitals of the Farbenfabriken vorm. Friedrich Bayer and Co., of Leverkusen, the Farbwerke vorm. Meister Lucius and Bruning, of Hochst, and the Badische Anilin- und Sodafabrik, of Ludwigshafen, are each to be raised from 252 to 430 million marks, *i.e.*, from about 12·2 to 21·5 million pounds at par (1 to 1·7 million pounds at the current rate of exchange); and the A.-G. fur Anilinfabrikation ("Agfa") in Berlin proposes to raise its capital from 88 to 146 million mk. Thus, these four companies are to increase their combined capitalisation by 622 million marks (£31,100,000 at par). A large proportion of this sum is to be allocated to supply the future capital requirements of the German nitrogen works at Oppau and Merseburg, and the remainder is ear-marked for renewals and repairs, which in some works were not carried out during the war, and for re-converting certain factories to peace-time production. This policy of capital enlargement is also being pursued by other companies, *e.g.*, the Fabrik Griesheim-Elektron proposes to increase its capital from 63 to 108 million mk., and Leopold Cassella and Co., in Frankfurt, from 113 to 185 millions. A comparison of these enormous figures, together with the sums expended on dividends in 1920–21 and the large amounts placed to reserves, with the corresponding figures for the period 1913–18, shows the undermining effect of the depreciated currency. The following are the official figures for the market values of German chemical securities in 1913, 1914, and 1918, in millions of marks:—

	1913.	1914.	1918.
Shares	19·7	2·8	14·3
Debentures, etc.	4·5	8·7	24

The division of the share capital and the dividend records of seven of the chief companies are given below:—

	Ord. shares. million mk.	Pref. shares. million mk.	Dividends (%). 1918.	1919.	1920.
Badische	180	72	12	18	20
"Agfa"	63	25	12	18	20
Elberfeld	180	72	12	18	20
Griesheim-Elektron	45	18	7	12	—
Höchst	180	72	12	14	20
Kalle & Co.	6	—	7	14	—
Weiler-ter-Meer	16·6	6·7	10	12	15

In judging the significance of the large profits and dividend disbursements, it is necessary to take into consideration the depreciated currency and the fact that the plant and machinery were acquired before that depreciation took place. The shares of the "Agfa" company are quoted at 435—535 (for the 100 mk. share) so that the dividend represents only a very small return on the invested capital at its current value. Nevertheless, the figures show that the year 1920–21 was on the whole a satisfactory one. Recently the threatened "sanctions" have much increased the difficulties of production. For months past sales have been declining; in some works stocks have accumulated, and purchasers have been demanding larger and longer credits. Prices, too, have fallen without any corresponding decline in costs of production, and a few plants have temporarily closed down. The imperative necessity for making large allocations to plant depreciation has been strongly urged by Dr. Duisberg, on the ground that the amounts now being written off are paper values, whereas the existing plant and apparatus were mostly purchased on a gold basis. For example, the depreciation of a plant which cost 1 million mk. five years ago would in normal times be reckoned at 10 per cent. per annum; but this assumes that at the end of 10 years the plant could be renewed for another million. If, however, as at the present time, the cost of renewal is 10, 15, or 20 millions, it is obvious that a writing off at the rate of 100,000 mk. per annum is quite inadequate.

"Aluminium and Bauxite."—Like the other publications so far issued by the Imperial Mineral Resources Bureau, this pamphlet deals with the war period, in which are included the years 1913—1919. Its chief interest lies in the information it supplies as to the developments which have taken place in various new bauxite fields. Some of these had not reached a productive stage when war broke out and others had barely started to produce. At that time bauxite was only mined on a large scale in France and the United States, but British Guiana, Yugoslavia, and Rumania have since become important producers of the ore, whilst preparations for production are in an advanced state in Dutch Guiana and India. The pamphlet opens with some brief notes on the properties of aluminium and with a list of the chief aluminium minerals. The mineral cryolite is then discussed shortly, and here it is of interest to note that no deposits of this aluminium ore have been found other than the well-known bed in Ivigtut, in South Greenland. A general statement follows on the properties of various classes of bauxite, and attention is drawn to the qualities required according to the use to which the mineral is to be put, *i.e.*, for the production of metallic aluminium, the manufacture of aluminium salts, of refractories or of abrasives.

The section which purports to deal with the uses of the metal will not convey much information, but from the first tables given the interesting conclusion may be drawn that the world's production of aluminium rose from 71,000 tons in 1913 to 170,000 tons in 1918. It is particularly noteworthy that the great increase in the demand which these figures indicate did not call into being any new successful process either for the production of refined alumina or for the reduction of alumina to metallic aluminium.

The occurrence and production of bauxite, the production, imports, and exports of aluminium, and other statistical matter are dealt with in a series of sections devoted to the following countries:—The United Kingdom, Gold Coast, Canada, British Guiana, India, Australia, France, Germany, Italy, Yugoslavia, Rumania, Spain, Switzerland, United States, and Dutch Guiana. Perhaps the most striking facts cited in this part of the pamphlet are the rapid development which has taken place in the productive capacity of the United States and the relatively still larger increase in the Norwegian smelting installations (Norway is not separately dealt with), whilst Germany has only become a serious producer of aluminium during the period under review. The discovery and exploration of extensive deposits of very high-grade ore in the Gold Coast are also notified.

The pamphlet concludes with a bibliography of the literature of the subject during the period dealt with. This is divided into sections on the Occurrence, Distribution, and Mining of Bauxite, The Metallurgy and Metallography of Aluminium, the Alloys of Aluminium, and, finally, the Uses of the Metal and its Compounds.

The Bauxite Industry in British Guiana.—The Demerara Bauxite Co., a British undertaking, has suspended operations on account of the small demand for the mineral in the United States, and an American company is also reported to have closed down for the same reason. The output of both companies has been shipped entirely to the United States, the quantity exported in January last being 8260 tons, valued at $43,169.—(*U.S. Com. Rep.*, *Apr.* 6, 1921.)

Advance Statistics of Production, Exports and Imports of Certain Metals, etc. in 1920.—The Imperial Mineral Resources Bureau has compiled the following advance statistics of production, exportation, and importation in respect of lead, zinc, silver, copper, tin, iron, and arsenic for the year 1920 (long tons throughout):—

Production in 1920.

United Kingdom.

	Long tons.
Pig iron	8,007,900

The Dominion of Canada.

Copper	36,230
Iron, pig, from Canadian ore	67,740
Iron, ore, sold for export	7,013
Lead	15,172
Silver	12,793,541 oz.
Zinc	17,931
Arsenic, white, and in ore	2,150

Australia.

Copper, bar	24,069
In blister	2,000
In ore exported	115
Lead	4,077
Lead bullion	1,939
In lead concentrates exported	4,122
Zinc	9,655
Tin	4,108
Iron, pig	344,000
Arsenic	1,202
Silver	701,177 fine oz

Federated Malay States.

Tin	34,934

Union of South Africa.

Arsenic, white	10
Copper ore and concentrates	9,710
Iron ore	2,289
Lead ore	524
Tin	2,189
Zinc ore and concentrates	2,097
Silver	892,205 oz.

South Rhodesia.

Arsenic	390
Copper, blister	2,775
Tin	4
Silver	158,982 oz.

Northern Rhodesia.

Copper (finished)	130
Lead	14,602
Silver	5,601 oz.

Nigeria.

Tin concentrates	6,022

Belgium.

Raw steel (ingots, etc.)	1,214,121
Finished steel	1,055,580
Finished iron	192,429
Zinc	81,711

France.

Arsenic ore	515
Copper ore	367
Lead ore	4,731
Zinc ore	4,179
Tin ore	20
Iron ore	13,648,257

Italy.

Copper	6,258
Lead ore (including argentiferous)	35,741
Zinc ore	96,514
Silver ore	492
Cupreous iron pyrites	4,329

Cuba.

Copper	7,366

Mexico.

Arsenic	1,180
Silver	33,112,571 fine oz

United States.

Arsenic . . about	6,000
Copper—	
Smelter output from domestic ores	551,339
Refinery production of new copper from domestic and foreign ores	702,232
Iron ore	67,773,000
Iron, pig	36,750,000
Lead (refinery statistics)	469,322
Silver	56,564,504 fine oz.
Zinc (reports of ore-smelters only)	428,368

Chile.

Copper	106,000 to 110,000

Dutch East Indies.

Tin	13,994

Exports in 1920.

From the United Kingdom.

Pig iron.

To—	Long tons.
Sweden	19,320
Germany	24,484
Netherlands	31,172
Belgium	181,191
France	59,316
Italy	80,652
Japan	26,574
United States	72,558
British East Indies	14,241
Australia	1,127
Canada	3,689
Other countries	65,131
Total	579,455

Lead.

To—	
Russia	617
Sweden	2,223
Germany	421
France	1,473
China (including Hongkong)	780
Japan	2,111
United States	2,998
British South Africa	247
British East Indies	5,331
Canada	7,144
Other countries	11,283
Total	34,628

Zinc (crude and manufactures).

Total	10,308

Copper (plates, rods, bars, blocks, cakes, etc., and manufactures of all sorts).

To—	
Sweden	252
Norway	983
Germany	46
Turkey	873
Brazil	464
Egypt (including Anglo-Egyptian Sudan)	3,600
India	7,996
Straits Settlements*	305
Ceylon	93
Australia	1,261
New Zealand	585
Netherlands	533
Belgium	1,409
France	1,758
Italy	4,101
British East Indies	2,736
Other countries	13,360
Total	40,355

* Including Federated Malay States and Labuan.

Tin (blocks, ingots, bars and slabs).

To—	
Russia	116
Sweden	999
Germany	214
France	1,808
Turkey	370
United States	3,637
Canada	1,113
Other countries	5,078
Total	13,335

From the Dominion of Newfoundland.

Iron ore	510,600

From the Federated Malay States.

Tin	34,934

From the United States.

Spelter from foreign ore	28,500	
Spelter from domestic ore	86,000	
Total		114,500
Copper refined		187,628
Ferro-manganese		3,454
Ferro-silicon		632
All other pig iron		212,742

From Bolivia.

Tin (West Coast shipments only)	29,542

From China.

Tin	11,795

From the Dutch East Indies.

Tin shipments	11,661

From Algeria.

Iron ore	1,096,527
Copper ore	591
Lead ore	12,598
Zinc ore	12,598

IMPORTS IN 1920.

Into the United Kingdom.

Pig iron (acid, basic, forge and foundry).

From—	Long tons.
Sweden	29,328
United States	20,574
Other countries	164,407
Total	214,309

Zinc, crude and manufactures (including rolled sheets and plates).

Total	116,891

Lead (pig and sheet).

From—	
Spain	58,149
United States	9,756
Mexico	1,049
Australia	57,987
Other countries	35,909
Total	162,850

Copper (bars, blocks, ingots, plates, sheets, etc.).

From—	
Australia	22,877
United States	37,817
Chile	13,323
Other countries	38,461
Total	112,478

Tin (blocks, ingots, bars and slabs).

From—	
Straits Settlements and Federated Malay States	15,435
Australia	1,701
Other countries	11,613
Total	28,749

Into the United States.

Totals—	
Zinc ore	23,000
Spelter	207
Tin	50,563
Ferro-manganese	59,254
Ferro-silicon	13,909
All other pig iron	123,201

State Assistance for the Brazilian Vegetable-Oil Industry.—The Brazilian Minister for Agriculture, Industry and Commerce has been authorised by the Government to negotiate with five leading firms for the erection of cottonseed presses and by-product plant in the States of Pernambuco, Parahyba, Ceara, Maranhao, and Pianhy. The Government will advance up to 75 per cent. of the outlay involved, provided that the plant is delivered ready for erection by December 31. The capacity of the cottonseed-oil plant must be at least 120 metric tons per month for small and from 430—600 t. for large works, and provision must be made for the eventual manufacture of soap, etc. Drugs, chemicals, plant, etc. required for the factories will, when imported, be given the same preferential treatment as goods imported for other State-supported enterprises. The five companies are as follows:—Sociedade Algodoeira de Nordeste Brasileiro, Companhia Parahybana de Beneficiamento e Prensegem de Algodao, Companhia Pastoril Agricola e Industrial Pianhyense, Philomemo Gomes Filhos, and Germano Boettcher. A large part of the production will probably go to the South-American markets, but doubtless other world markets will feel the competition.—(*Chem. Ind., Mar.* 28, 1921.)

The Title of "Civil Engineer."—The Institution of Civil Engineers recently attempted to protect the title "civil engineer," but without success, on account of the difficulty of including engineers of high professional standing who were not members of the Institution. Now the Institution is applying to the Privy Council for a supplementary charter to enable it to confer the title "chartered civil engineer" as a recognised mark of professional status.—(*Min. Mag., Apr.*, 1921.)

PERSONALIA.

M. Georges Claude has been awarded the gold medal of the Société d'Encouragement au Progrès.

The readership in electrochemistry in the University of Manchester has been filled by the appointment of Mr. A. G. Lobley.

The "Sir Robert Hadfield Prize, 1921," has been awarded by the Council of the Institution of Mechanical Engineers to Mr. H. Moore for his paper on "A Small Ball-Hardness Testing-Machine."

Mr. J. E. Sears, jr., has been appointed Deputy Warden of Standards in succession to Major P. A. MacMahon, who has retired. Mr. Sears will continue to hold the post of Superintendent of the Metrology Department at the National Physical Laboratory.

Dr. E. F. Nichols has been appointed president of the Massachusetts Institute of Technology. He was formerly professor of physics at Yale University and is now director of research to the National Electric Lamp Association, Cleveland, Ohio. Dr. H. Hibbert, assistant professor of chemistry in Yale University, has been appointed to an associate professorship in applied chemistry. Dr. A. E. Taylor, professor of physiological chemistry in the University of Pennsylvania, and Mr. J. S. Davis, assistant professor of economics at Harvard, have been appointed directors of the Food Research Institute (*cf.* J., 1921, 129 R).

The German Chemical Society has presented to Prof. Dr. Carl Duisberg a silver medallion in recognition of his great services to the Society and to chemical science.

The following academic appointments, etc. are reported from Germany:—Dr. E. Fromm, extraordinary professor of chemistry in the University of Freiburg (Breisgau), to be professor in the medical faculty at Vienna; Dr. A. Wisner to the professorship of chemical technology in the German Technical "Hochschule" in Brünn; Prof. Dr. Binz of Frankfurt to be professor of chemistry in the Agricultural "Hochschule" in Berlin; and Dr. J. Meyer, professor of chemistry in the University of Breslau, to succeed Prof. W. Biltz as professor in the School of Mines (Bergakademie) at Clausthal. Dr. Hermann Ost has retired from the chair of chemical technology in the Technical "Hochschule" at Hannover.

Dr. Henri St. George, one of the best-known chemists and bacteriologists in Eastern Canada, died suddenly on April 1.

Dr. T. Lynton Briggs, who joined this Society in 1885, died on April 3 at Flushing, New York, aged 63 years. He emigrated to America in 1886 and worked in the research department of the General Chemical Co. His father was one of the first to manufacture coal-tar dyes in England.

The death is announced of Dr. J. I. D. Hinds, chemist to the Geological Survey of Tennessee, at the age of 73. Dr. Hinds assisted in founding the American Chemical Society, and was professor of chemistry in Cumberland University and the University of Nashville and Peabody College.

The death is reported of Prof. T. Miyake of the Agricultural College of the Imperial University, Tokyo.

The deaths of the following German chemists and chemical technologists have recently been announced:—Prof. E. Kirchner, a well-known authority on the technology of paper manufacture, on February 14, in his 74th year; Dr. Carl Duttenhofer, one of the leaders of the German explosives industry, on March 15, in his 72nd year; and Dr. Alex. Bauer, formerly professor of general chemistry in the Technical "Hochschule" in Vienna, aged 85 years.

PARLIAMENTARY NEWS.

HOUSE OF COMMONS.

The Budget.

The Budget for 1921–22, introduced by Mr. A. Chamberlain, contained no new pronouncement of importance to chemical manufacturers. As previously announced by him, the excess profits duty, which yielded £219,000,000 in the past financial year, is abolished, but income-tax, corporation tax, duties on beer and spirits, and postal rates remain unchanged. The corporation profits tax gave a disappointing yield of £650,000, instead of the anticipated £3,000,000. No additional taxation is to be imposed. The external debt has been reduced by £117,000,000 to £1,161,560,000, and the only debt outside the United States and Canada is £826,000 in Sweden, which will be paid this summer. Total revenue and expenditure last year were £1,425,985,000 and £1,195,428,000, and for the current year they are estimated at £1,216,650,000 and £1,038,728,000, respectively.—(Apr. 25.)

Postal Rates on Scientific Journals.

Mr. Rawlinson asked the Postmaster-General whether, in view of the importance of scientific journals and the fact that they cost no more to carry than newspapers of equal weight, he would allow scientific journals published fortnightly or monthly to be registered and carried at the same rate as newspapers.

Mr. Pease replied that similar suggestions had often been considered and rejected. The newspaper rate was already unremunerative, and the proposed measure would considerably increase the existing loss. Such an extension could not be restricted to scientific journals and would have to include magazines and other periodicals.—(Apr. 26.)

Gretna Factory.

Replying to Major W. Murray, Sir L. Worthington-Evans said that the future of Gretna Factory depended upon the settlement by the Government of the general policy regarding the national factories. The subject, which raised issues of the highest importance, was under consideration by the Cabinet, and a statement would be made as soon as a decision had been reached.—(Apr. 29.)

Government Laboratory (Salaries).

Answering Major Hills, Mr. Young said that the initial scales for future entrants to the chemical assistants' grade in the Government Laboratory would be £160 10s.—£200 for men and £140 10s.—£180 for women; the latter scale would come into force when any new women chemical assistants were engaged.—(May 2.)

Power Methylated Spirits.

Mr. Young, in reply to Sir W. Pearce, said that the allowance of 3d. per gallon on spirits used in making industrial or power methylated spirits represented the cost of excise restrictions to the home distiller. There was no reason to think that this allowance was insufficient and it could not be amended.—(May 2.)

Rubber Output (Federated Malay Straits).

In a written answer, Mr. Wood informed Major Boyd-Carpenter that proposals for legislation to restrict the output of rubber in Malaya had been submitted, but it had been decided that such a policy would involve financial liabilities which the Federated Malay Straits could not afford and would necessitate undue Government interference. Conditions must therefore be allowed to right themselves.—(May 4.)

Dangerous Drugs Act.

In answer to Mr. Gilbert, Mr. Shortt stated that the Committee on the Regulations under the Dangerous Drugs Act had nearly completed its inquiry. The report was expected shortly, and would be published.—(May 4.)

REPORTS.

INTRODUCTION TO THE REPORT OF THE BRITISH MISSION APPOINTED TO VISIT ENEMY CHEMICAL FACTORIES IN THE OCCUPIED ZONE ENGAGED IN THE PRODUCTION OF MUNITIONS OF WAR IN FEBRUARY, 1919. *Pp.* 10. *H.M. Stationery Office.* 1921. [*Cmd.* 2*d.*].

The first section of this paper gives a list of the factories visited by Brig.-Gen. Hartley's Mission, together with a few notes on the "Interessengemeinschaft." German methods of manufacturing explosives and poison gases form the subject matter of the second. Mr. W. Macnab and Mr. S. I. Levy found that the German methods of making explosives were very similar to those in use in this country, the chief differences arising from the shortage of materials due to the blockade, *e.g.*, plant for making ammonia from nitric acid, the use of paper crêpe in preparing nitrocellulose, and the substitution of glycol for glycerin (which was apparently not very satisfactory). The strong-acid method was employed for manufacturing picric acid, and *m*-nitrotoluene was separated from the mixed mono-isomers by fractional distillation *in vacuo*, thus allowing of the production of relatively pure TNT without later purification. Apart from these two instances, it may be said that the German methods of explosives manufacture, as seen, were not superior, and in some cases were inferior, to those used in the large English national factories. Dr. H. Levinstein and Mr. F. H. Carr were impressed by the fact that the bulk of the plant for producing poison gas had been used before the war in the manufacture of dyestuffs or pharmaceutical products; and also by the way in which the various stages of manufacture had been allocated among the factories according to the suitability of the available plant. The third section summarises the output of initial products, explosives and gases in the factories visited (*cf.* J., 1919, 398 R); the fourth deals with the military importance of the German chemical industry; and in the final part the position, in February, 1919, of the British and German chemical industries is reviewed [*cf.* J., 1919, 285 R, 303 R (Allmand), 408 R, 427 R (J. Allan), 468 R (Carr); and 1920, 47 R (Evans, Walpole)].

REPORT ON THE COMMERCIAL SITUATION IN SIAM AT THE CLOSE OF 1920. *By* T. H. LYLE, *H.M. Consul-General, Bangkok. Pp.* 42. *Department of Overseas Trade. London: H.M. Stationery Office.* 1921. *Price* 1*s.* 3*d.*

The bad trading and financial conditions prevailing throughout the world have also affected Siam, and there is little new to chronicle since the issue of the last report (*cf.* J., 1920, 300 R). A Siamese company, the Siam Coal Mining Co., Ltd., has been formed to exploit a concession near Trang, where coal has been found, but some difficulty is expected as the coal will not bunker, being liable to ignite spontaneously after a short exposure. An old-established British company has recently acquired temporary control of one of the tannery undertakings, with option to purchase should the venture prove promising.

The export of teak during the 12 months ended March 31, 1920, was practically double that of the previous year, but rice was exported in smaller quantities owing to the partial failure of the crop. The exports amounted in value to £15,718,170 (£1 = 11·28 ticals), and included:—Rice and rice products, 441,039 tons (£10,911,586); teak, 70,202 t. (£1,189,801); hides, £331,472; stick lac, 1063 t. (£156,430); sapphires and rubies, rough, £234,312; sugar, red, 4272 t. (£155,780); and salt, 62,428 t. (£80,733). Imports were valued at £12,272,967, of which the United Kingdom furnished 17·1 per cent. and the British Empire 74 per cent. Importation of iron, steel and machinery from the United Kingdom is steadily increasing, but Japan is losing ground, except in regard to enamelled goods, of which the imports have doubled. The chief articles imported, together with the percentage furnished directly by Great Britain, were as follows:—Glass manufactures, £64,621 (10%); china and earthenware, £146,539 (2·4%); chemicals, £51,384 (31·8%); copper, zinc, iron, lead, tin and other metals, £86,242 (35·3%); coal and coke, 15,545 t.; oils, other than petroleum, £126,211; medicines, £188,085 (8·9%); paper, £252,316 (32·1%); matches, £209,366; leather and manufactures of, £50,222 (14·4%); soap, £45,799 (71·2%). Prospects of improving British trade with Siam appear to be good. The report contains very full statistical tables of imports.

COMPANY NEWS.

LEVER BROTHERS, LTD.

The twenty-seventh annual general meeting was addressed by the chairman, the Rt. Hon. Lord Leverhulme, on April 22 at Port Sunlight. After referring to the good services of Mr. John Gray as vice-chairman, from which position he has retired to become chairman of Messrs. Gossage, of Widnes, and Messrs. John Knight, of London, the chairman commented on the precipitous deflation of prices which had occurred and expressed his belief that prices had now sunk to zero. He then spoke of the company's new capital arrangements (*cf.* J., 1921, 95 R, 134 R) and financial position, stating that the Niger Company had been purchased during the past year for 8½ million pounds, Price's Candle Co. for 1¼ millions, Gossages and Crosfields for 1 million, and John Knight, Ltd., for about half a million, making a total of 11¼ million pounds. Negotiations were entered into with the African and Eastern Corporation, but in view of the entirely changed conditions in West Africa, the scheme agreed upon had been abandoned by mutual consent. All new development work had been stopped.

Trade at present was in a most unsatisfactory state; the home trade of the soap industry had probably suffered less than that of most other industries, but export business was extremely quiet. There was a general slump in West African produce, and the position of the Niger Co. had been made more difficult owing to the mistaken policy of the directors of that company during the half-year prior to the change of control. With a view to supporting their own market, the Niger directors had made purchases of native produce through brokers in the open market, and when the slump came heavy losses resulted; during this time Lever Bros., anticipating the coming fall, were selling forward, and after the fusion of the two companies had been effected it was discovered that their profits on sales at high prices were offset by the losses of the Niger Co. The property acquired from the latter company was extremely valuable, and if it ever became necessary to sell it—which is not contemplated—there would be no difficulty in obtaining a foreign purchaser at a price which would entail no loss to Lever Bros. Prospects for 1921 were bright. Helped by the withdrawal of Government interference and the excess profits duty, there was a great revival in the home trade and the beginning of a revival in the overseas trade.

During the war Lever Bros. and its associated companies (now 158) supplied the Government with over 60,000 tons of glycerin at the controlled price of £59 10s. per ton, compared with £200—£500 per ton paid for the imported product, and it was estimated that the total advantage to the Government of having this large home supply represented a money gain of over £10,000,000. Although by virtue of the production of glycerin, the soap industry was a "key" industry, there was no desire to keep out overseas competition by protective tariffs; absolutely free-trade conditions were to be preferred. For the first time in its history the company had experienced a strike. The employees had recently agreed to a reduction in wages; the total sum disbursed in wages by the parent and associated companies in 1920 was £7,707,031, whereas that paid in dividends to the ordinary shareholders was £456,000. During the period July, 1914, to December, 1920, £3,760,814 had been paid in income tax. In reply to questions, Lord Leverhulme said that the recent issue of debentures was made to reduce the outstanding liabilities, which amounted to about £8,000,000, and that the company's claim for repayment of excess profits duty would be a very heavy one.

Associated Portland Cement Manufacturers, Ltd.—The accounts of this company for 1920 show a record revenue, after allowing for taxation, of £952,531, a sum which includes investments in associated companies, etc. Issued capital amounts to £4,422,040 and debentures stand at approximately £4,000,000. There is a general depreciation fund of £1,050,000 and other reserves amount to £661,000. The dividend for the year is 10 per cent. or 2 per cent. better than for the previous year and £221,561 is carried forward, against £143,51[illegible] brought in. The position and prospects of th[e] cement industry were outlined by the Hon. F. [illegible] Stanley at the annual meeting held in London o[n] April 26 (*cf.* J., 1921, 156 R).

Tharsis Sulphur and Copper Co., Ltd.—Address[-]ing the annual meeting of this company on April 2[illegible] in Glasgow, Mr. W. P. Rutherford, who ha[s] succeeded the late Lord Glenconner as chairma[n] attributed the very low prices ruling in the copp[er] market to the existence of an unprecedented amou[nt] of scrap material and the general lack of deman[d]. A gradual improvement, however, was to [be] expected, and the company's mining resources [in] Spain were ready to meet whatever demand aro[se] for its ores when markets returned to their pre-w[ar] activity; but as long as the present stagnati[on] lasted the company would restrict expenditure [as] far as possible. A dividend of 15 per cent. w[as] passed.

The Salt Union, Ltd.—The annual meeting [of] this company was held on April 19 at Liverpo[ol]. Mr. G. H. Cox, the chairman, in a review of t[he] position and prospects of the salt industry, sa[id] that output had been very seriously reduced, t[he] number of pans now working being only 45, co[m-]pared with 245 a year ago. Thanks to better sh[ip-]ping facilities, the Eastern trade had improved [in] 1920, no less than 100,000 tons of salt having be[en] delivered to Calcutta, besides 5000 t. to Rango[on]. But prospects in the Indian market had darke[ned] owing to the competition of German crushed r[illegible]

from Hamburg and solar salts from Port Said, Spain, and the Red Sea. No English salt had been shipped for two months, but now a limited business was being done, and prices were more satisfactory. Exports to Japan amounted to 6000 t. in 1920, and recently 18,000 t. had been shipped, in the production of which the Weston Point vacuum plant had furnished 4593 t. of salt in one week. Prospects in Scandinavia and in many other export markets were adversely affected by German competition, which was much helped by the abnormal position of the German exchange. The good export trade in 1920 justified the company in maintaining the dividend of 15 per cent. on the ordinary shares.

TRADE NOTES.

BRITISH.

South African Imports of Chemicals in 1919.—The measure of South Africa's dependence upon other ountries for supplies of chemicals and drugs may e gauged from the following table of imports durng the year 1919. The third column gives the perentage weights in long tons (or volumes) of the ubstances obtained from the countries indicated:—

		Quantities.	Countries of origin Per cent.
cetone, methyl alcohol, wood alcohol..	galls.	8,661	U.K. 24·8, U.S. 30, Canada 45.
:ids:—			
Acetic..	..	1,745	U.K. 34·8, U.S. 27·4, Japan 37·7.
Boric	tons	18·8	—

Items in italics are given in values (dollars) only.

By value the United Kingdom contributed about } per cent. of the total imports.—(*U.S. Com. Rep.*, *ar.* 12, 1921.)

Mauritius in 1919.—The sugar industry was very 'osperous in 1919, and prices exceeded all previous andards. The high-water mark of production has, wever, been reached, as practically all the areas itable for cane growing are already under the op, and any increase in production will probably me through improved methods of cultivation and illing. Of the total area under cultivation, 6,091 acres, no less than 175,923 acres was under gar. Cultivation of aloes fibre declined, and the ndency to plant sugar-cane on land formerly cupied by aloes continued. Increasing attention was paid to the possibilities of growing sisal, and trial plantations were established, but the planters were not enthusiastic. Sugar-cane megass is an excellent paper-making material, but hitherto it has been used as fuel in the sugar factories, and as such its value is only equivalent to that of the fuel it replaces. The value of imports during 1919 was Rs. 47,037,024, of which the United Kingdom supplied 24·3 per cent., compared with 16·3 per cent. in 1918 (rupee = 1s. 4d. at par). Imports of coal, machinery, sulphate of ammonia, and linseed oil from the United Kingdom declined, and the high freight rates drove some of the trade to British possessions, particularly South Africa. The value of imports from the United States and Japan also diminished. Exports were valued at Rs. 127,806,321, of which 75 per cent. went to the United Kingdom; they included:—Sugar, 302,826 metric tons; aloes fibre, 2176 t.; copra, 234 t.; coconut oil, 2411 hectolitres; vanilla, 2995 kg.; and molasses, 103 t. (*cf.* J., 1920, 437 R).—(*Col. Rep.-Ann.*, *Cmd.* 1103–5, *Feb.*, 1921.)

FOREIGN.

Foreign Trade of Japan in 1920.—A comparison of the Japanese trade statistics for 1919 (*cf.* J., 1920, 327 R) and 1920 shows that the value of the total imports rose from £221,692,930 to £238,286,178, and that the total exports declined from £214,084,842 to £198,735,678, the decrease being accounted for mainly by semi-manufactured goods. The values of imported and exported chemical products are given below, together with the percentage increases or decreases over those in 1919, the yen being taken at 2·04s.:—

	Imports, 1920. £	Inc. or dec. over 1919. Per cent.
Sugar	6,142,440	+ 3·5
Salt	1,673,922	– 13·7
Oil-bearing materials	1,691,262	– 21·9
Hides and skins	1,975,842	+ 25·3
Rubber and gutta-percha, crude.	1,368,234	– 22·7
Chile saltpetre	2,523,480	+ 78·8
Ammonium sulphate, crude ..	2,026,944	– 27.6
Oilcake	15,392,718	+ 11·6
Coal	2,031,126	+ 7·1
Ores	1,627,614	– 23·7
Leather	857,208	+ 53·3
Paraffin wax	770,202	+ 9·1
Caustic soda and soda ash ..	1,185,444	– 20·0
Coal-tar dyes	1,574,778	+ 44·0
Paper-pulp	1,344,870	+ 23·4
Iron, pig, rod, tube, plate, etc..	26,342,112	+ 12·4
Lead, ingot, slab	725,118	– 34·8
Tin, ingot, slab	758,982	+ 7·0
Petroleum	2,169,540	– 1·9
Paper	1,794,282	– 4·6

	Exports, 1920. £	Inc. or dec. over 1919. Per cent.
Starches	509,694	– 60·8
Sugar, refined	3,121,592	+ 41·5
Coal	4,610,400	+ 19·9
Oils, vegetable	1,082,628	– 18·9
Camphor	506,430	– 37·0
Iron	1,503,684	– 30·6
Copper	1,294,278	– 51·5
Leather manufactures	319,566	– 52·5
Soaps	465,426	+ 4·3
Matches	2,902,206	– 13·7
Papers	2,359,056	– 8·9
Cement	1,025,618	+ 53·7
Pottery ware	3,208,512	+ 39·0
Glass, and manufactures of ..	2,350,378	+ 18·0
Rubber tyres	817,734	+ 12·7

The importation of precious metals increased, in spite of the fact that the unfavourable balance of trade in 1920 was five times as great as in 1919.—(*U.S. Com. Rep.*, *Feb.* 16, 1921.)

Austrian Foreign Trade in 1920.—The foreign trade of Austria for the fiscal year 1920 amounted by weight to 5,479,230 metric tons, of which 1,992,990 t. represented the trade between Austria and Germany. Germany supplied 40 per cent. of the total imports (4,502,170 t.) and took 20 per cent. of the exports (977,060 t.). Certain of the principal im-

ports and exports are given below, in metric tons, for the period July 1, 1919, to June 30, 1920:—

	Imports. Metric tons.	Exports Metric tons.
Coal	2,191,200	—
Celluloid	110	—
Magnesite	—	55,200
Graphite	—	6,880
Glass and glassware	18,500	—
Cement	—	10,600
Pottery	27,700	21,200
Chemical materials and products	43,600	35,320
Dyes, varnishes, and medicines	2,100	—

The total values of the imports from, and exports to, Germany were 13,427 million and 5,419 million kronen, respectively (krone=10d. at par, now about 0·18d.).—(*U.S. Com. Rep., Mar.* 21, 1921.)

Swiss Imports of Chemicals and Oils in 1920.—Importations of chemicals and oils into Switzerland in 1913 and 1920 were as follows:—

	1913. Metric tons.	1920. Metric tons.
Sulphur, lump, etc.	33·88	38·62
Turpentine oil	19·32	17·05
Caustic soda and potash	89·06	115·71
Sulphuric acid	96·11	132·8
Copper sulphate	21·03	8·68
Benzine	160·88	349·2
Aniline	12·02	23·46
Aniline compounds	8·87	15·23
Alcohol, denatured	13·36	15·91
Linseed oil	47·69	20·9
Olive oil, olein	6·27	5·54
Fats and oils, liquid, crude	28·67	9·92
Coconut and palm oil, crude	21·91	18·26
Petroleum	629·42	246·12
Lubricating oil	138·9	122·03
Bone meal, raw phosphates	188·85	187·17
Basic slag	557·93	651·45
Potash fertilisers	132·41	166·31
Other fertilisers	263·09	167·32

—(*Chem. Ind., Mar.* 28, 1921.)

GOVERNMENT ORDERS AND NOTICES.

Prohibited Exports.—The following have been removed from the list of prohibited exports, as from April 28:—(1) Potash, caustic, and articles containing caustic potash; (2) Potassium carbonate and mixtures containing potassium carbonate.

Orders under the German Reparation (Recovery) Act, 1921.—Order No. 6, dated April 21, excludes from the provisions of the Act articles produced or manufactured in the Saar Basin.

By Order No. 7 of April 28, any article proved to have been delivered by Germany to any Allied or Associated Power by way of reparation is exempted from the provisions of the Act.

Order No. 8, of May 3, exempts any article imported before June 15, 1921, provided it is essential for completing and working machinery or plant partly delivered before March 8, 1921, or is an essential part of German machinery installed in the U.K. before that date; and if patterns, drawings, or designs were sent to Germany before March 8, provided that their value is not less than 20 per cent. of that of all articles to be manufactured under the contract.

Order No. 9, dated May 3, exempts any article sent from the U.K. to Germany, or returned unaltered to the U.K. from Germany, provided that the consignor in the U.K. still retains the ownership.

In Order No. 10, of May 3, sections (a) and (b) of Order 1 (*cf.* J., 1921, 155 R) are recapitulated, and the date up to which importation is allowed is extended to June 15.

Women and Young Persons (Employment in Lead Processes) Act, 1920.—Draft Orders have been issued by the Home Secretary under Section 2 of the above Act, providing that any women or young persons employed in any process in which dust or fume from a lead compound is produced or in which such persons are liable to be splashed with any lead compound must be examined once in every three months by the district Certifying Surgeon appointed under the Factory and Workshop Act, 1901, and that suitable cloakroom, messroom, and washing accommodation shall be provided. These proposed Orders are based on the requirements in existing Regulations and Orders for other processes.

Emergency Regulations.—By Royal Proclamation of April 30, the state of emergency proclaimed on March 31 and the Emergency Regulations of April 1 were continued.

The supply of coal to breweries and distilleries, except to certain yeast-producing distilleries, has been prohibited.

OFFICIAL TRADE INTELLIGENCE.

(From the Board of Trade Journal for April 28 and May 5.)

OPENINGS FOR BRITISH TRADE

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent.	Materials.	Reference number.
Australia	Skins, hides, glove leather	*412/20/7/545
British West Indies	Cement, paper	527
"	China	567
Canada	Chemicals	520
"	Gelatin	521
"	Soap, disinfectants, china	524
"	Crockery, china	525
"	Floor oil, washing compounds	†
"	Polishes	564
South Africa	Tinplate	565
"	Window glass, steel plates	566
Belgium	Paper	529
"	Pig iron, minerals, chemicals, cement, glass, china, crockery, paint, varnish, paper, leather	571
Danzig	Edible oils and fats, industrial and mineral oils	529A
France	Copra, groundnuts, oilseeds, crude drugs, hides, skins, tanning materials	532
Greece	Mexican fibre	533
Italy	Crude linseed oil	534
Netherlands	Fertilisers	535
Norway	Chemicals	537
"	Tinplate, steel sheets	538

Argentina	Earthenware	550
Cuba	Plate and window glass, tinfoil, crown corks	552
"	Paint, varnish	592
Mexico	China	593

* The Official Secretary, Commercial Information Bureau, Australia House, Strand, London, W.C. 2.

† The Canadian Government Trade Commissioner, 73, Basinghall Street, London, E.C. 2.

MARKETS SOUGHT.—A Canadian tannery able to export leather for bookbinders and bag makers, wishes to hear from importers in the U.K.

A Canadian tannery able to export 1000 sides per week of chrome leather in black and colours desires to get into touch with U.K. importers.

A firm at Montreal able to export asbestos wishes to hear from importers in the U.K.

[Inquiries to the Canadian Government Trade Commissioner.]

TARIFF. CUSTOMS. EXCISE.

Australia.—Drugs and chemicals, not elsewhere included, when packed for use in the household are dutiable under Item No. 79, and medicines for similar use under Item No. 285.

Austria.—As from April 15, customs duties when paid in bank notes must be paid at 80 times the rates specified in the tariff.

Belgium.—Sulphuric ether may be imported without licence as from May 2.

British Honduras.—The import duty on fuel oil has been doubled, and the export duty on alcoholic beverages reduced.

British India.—The valuations of raw hides and skins for export duty are set out in the issue for May 5.

Cyprus.—The export is prohibited to all destinations of, *inter alia,* chemicals, drugs, oils, copper, silver and gold.

Czechoslovakia.—A copy of the export free list may be seen at the Department, 18, Queen Anne's Gate, S.W. 1.

Denmark.—A "dispensation duty" is charged in connexion with the issue of licences for the import of goods containing sugar. A complete schedule of such duties may be seen at the Department.

Ecuador.—The export duty on ivory nuts is fixed, as from January 1, at 2 centavos per kg. for unshelled and 3 centavos per kg. for shelled nuts. Certain additional export duties are also levied thereon.

Egypt.—Exports to Russia are no longer subject to licence except in respect of goods the export of which is prohibited.

Recent import tariff valuations affect, *inter alia,* copper, brass, tin, lead, zinc, phosphor bronze, antimony, and quicksilver.

France.—The export duty on dephosphorisation slag has been withdrawn as from April 3.

Germany.—Import licences are no longer required for animal manures, and many seeds and condiments.

Export prohibitions have been withdrawn from raw cocoa, lemon juice, certain spices, white of egg, cocoa butter, rice starch, vinegar, certain flavouring essences and chemically prepared foods, etc.

Do. (Occupied Territory).—Not more than 5 kg. of goods (with some exceptions, including pharmaceutical products and synthetic dyes) may be imported by parcel post without licence.

Iceland.—The import is prohibited of chocolate, chinaware, liquorice, and perfumery. The import of almost all other goods is free.

Italy.—Until further notice all goods (with certain exceptions) may be imported by parcel post without licence.

Luxembourg.—All goods may now be exported without restriction with a few exceptions, among which are chemical and natural manures.

Mexico.—The export duty on sugar has been abolished.

Netherlands East Indies.—A copy of the new tariff law may be seen at the Department.

Increased import duties are payable on wares of iron, steel, tin, lead, copper, zinc, leather, and paper.

Modified export duties are payable on mineral oil and by-products thereof, and new duties on rubber, quinine, copra, and coconut oil.

New Zealand.—Export prohibitions have been withdrawn from glue, gelatin, glue pieces, hide pieces, and similar goods for the manufacture of glue and gelatin.

Nigeria.—The import duties on spirits have been increased.

Norway.—Export prohibitions have been withdrawn from certain hides and skins, leather, and pyrites.

Paraguay.—The import duties on starch, creolin, matches, common soap, and candles have been modified.

Rumania.—The export is prohibited of caustic soda, copper, brass, flax, flaxseed, grease, iron ore, pyrites, lard, animal fats, paper, paraffin wax, crude petroleum, petroleum residues, and zinc.

Special authorisation is required for the export of bones, cellulose, cement, ferromanganese, old iron, tarred paper, petroleum products not specified above, and shoemakers' glue and starch.

South Africa.—The import duties on beer and spirits have been increased.

Spain.—The export is permitted without restriction of all kinds of paper, cardboard and pasteboard.

The restrictions on the export of certain hides and skins have been relaxed.

The surcharge of customs duties when paid in Spanish silver or notes of the Bank of Spain is fixed for the month of May at 37·79 per cent.

Sweden.—Export prohibitions have been withdrawn from certain oilcakes and cattle foods.

A copy of the regulations affecting the testing of leather substitutes may be seen at the Department.

It is proposed to increase the customs duties on china, earthenware, glass, iron and metal goods.

Tunis.—Export prohibitions have been withdrawn from essence of turpentine and celluloid.

REVIEWS.

FACTORY ADMINISTRATION AND COST ACCOUNTS. *By* EDWARD T. ELBOURNE. *New edition. Pp.* xx.+ 811. *(London: Longmans, Green and Co. 1921.) Price 45s. net.*

One of the most interesting developments of recent years has been the attempt to place factory costs and management on a scientific basis. Just as in the chemical industry there has been a constant progress in the replacement of "rule of thumb" and empirical methods of manufacture by those based on exact knowledge, so in other branches of industry has there been an endeavour to replace rough estimates by accurate costings and to base management more on known statistical figures than by observation—more or less cursory—of the work in hand. There has been, moreover, a marked contrast in the progress of various industries, for while the engineering and heavy chemical trades have been firmly established, the dyestuff and fine chemical industries are still in the embryonic stage. In engineering the systems of costing and of factory control have been developed to a state of great efficiency, but only recently has the value of chemical control of material begun to be recognised. In the chemical industry the converse is possibly true, for there, after years of propaganda, the value of research and laboratory control is well established and extensively practised, but the vital necessity of accurate costings and the value of scientific management is but just beginning to be realised. Although the principles of control, chemical or otherwise, of experiment and research, of costing and of management are the same, whatever may be the industry, there is

a great difference in their application. Thus, in engineering, labour is the all-important item, and material costs are small in comparison, as, for instance, take the cost of a £1000 motor car and contrast the value of the metal used and of the labour involved: whereas in the chemical industry the value of the material employed is often many times that of the labour. This results in a different outlook in the two industries. In engineering, labour costs and rate of production are the factors most eagerly scrutinised, whilst in chemistry yields play the most important part in factory cost. Again in regard to expenses, whilst many are common to both industries, in engineering the cost of machinery and its output may be contrasted with the laboratory and supervision expenses in the chemical industry. It follows that though both the engineers and the chemists are agreed on the principles of costing and management, the application of these will be different in each case, and not only will they differ in each industry, but in each particular branch.

The chemical manager, therefore, who wishes for information on these important points can only expect to find general principles in the literature available, and must be prepared to work out the particular application suited to his works. He will be in much the same position as he finds himself with regard to his own science, for whilst he can get certain information from published chemical literature, he must amplify this and work out his methods in his research and technical laboratories and his own drawing office. With a recognition of these factors, many chemical managers welcomed the appearance of the first edition of "British Factory Administration and Accounts" in 1914, and will turn eagerly to the 1921 edition* to see what help in their industry they may derive from it. The author of these books has had great experience in some of the largest engineering undertakings in the world, and therefore speaks with authority on the practice in this industry, but the chemical manager will turn to the book to select those systems which can be successfully applied in his own particular works.

The preface promises well, emphasis is laid on the fact that the book deals essentially with principles and that practical applications are given by way of illustration; this underlying idea of the work is fully in keeping with the remarks previously made. It is also clear that the book is intended as one for reference. In this review it is intended to consider it from the standpoint of its value to one in charge of a chemical works. It consists of over 700 pages, with an excellent index of 60 pages. These are divided equally (approximately) into Works Management and Works Accounting, and the subjects are dealt with most exhaustively from an engineering point of view. The greater portion of the work, unfortunately for the chemical manufacturer, is occupied with the illustrations rather than by a discussion of principles, and these illustrations will, it is feared, prove of very limited application in the management of chemical works. It is proposed, therefore, to deal with these principles rather than with details of forms and methods specially applicable to engineering; also to consider the subjects as they are divided in the book itself.

1. *General Administration.*—There is very little in this section which will be helpful to the manager of a chemical works, though here and there items of interest crop up; for example, on page 18 the question of buying material is entirely looked at from the engineering standpoint, whereas in a chemical works the quality of the article very often determines its price and certainly its value to the manufacturer. On page 64 there is a very interesting statement regarding the relation of works expenses to direct wages, which is worth the careful attention of all concerned. The fallacy of using a ratio of works expenses to the direct wages bill as a measure of the efficiency of management is pointed out. It may be remarked that in a perfectly organised works where machinery is used to such an extent that the amount of direct labour is practically negligible, the proportion of expenses to direct labour would be enormous and, to the uninitiated, might excite the utmost alarm as to the efficiency of the management. There is a great deal of useful and general information in this section to those dealing with the administrative side of the business, such as sales, organisation of the office staff and legal points relating to the question of insurance, etc.

2. *Works Management.*—Divided into three sections of Production, Labour, and Material Control.

Production.—This section is a chapter of 12 pages relating to buildings and plant. It might very well have been extended, as it is a subject of very general interest, whereas the other chapters relate almost entirely to conditions existing in the engineering trade. The section on buildings and plant is so essentially a question in which every manufacturer is interested that it is a great pity it was not further elaborated.

Labour Control.—The relation of engineering employers with their employees and of the unions concerned has been developed to such an extent that the chemical trade will be very glad to obtain from them all the information possible, and therefore this section on labour administration will prove of very great interest to the chemical works manager, and will also prove most valuable for the purpose of reference. It is certainly one of the most useful sections in the book.

Material Control.—This section deals with the methods used in the engineering industry, and will prove but of very limited use to those engaged in the chemical industry.

3. *Works Accounting.*—Divided into two sections:—(a) Administration Records, (b) Cost Accounts, followed by specimen forms of works routine, with a complete index.

(a) *Administration Records.*—This is an extremely important section, and its relation to the all-absorbing question of cost accounts is well defined. In contradistinction to the earlier part of the work, this section is of general interest, and will well repay careful study by all concerned in factory management and accounting. It contains a full account of matters of importance to every factory, such as employment records and methods for the accurate keeping of all acounts relative to wages, stock and plant, as well as much valuable information as to stocktaking and depreciation and valuation of plant. Whilst the portion relating to depreciation is more particularly devoted to engineering, the whole section contains such a mass of general information that it will prove of the utmost service as a guide to what should be done in organising or reorganising a works, as well as a useful reference book on these subjects. The importance of accuracy in these matters, if a satisfactory costing system is to be installed, is brought out in the next section dealing with cost accounts.

(b) *Cost Accounts.*—It is not sufficiently recognised that accurate factory costs are essential to success. The result of a business run without these is that the owners do not know how they stand until their final yearly balance-sheet is made out; on the other hand, with an accurate costing system, although they may not know exactly how they are placed until the final balance-sheet is drawn up, they can form a fairly accurate opinion as to the way things are tending all through the year. Such a system to be a success, however, means close co-operation between the business and technical managers and the accountants, and it costs money which, because it does not show direct results, is

often begrudged by short-sighted proprietors. Consequently, Section VI. A. is of vital importance to proprietors, or the financial management, as well as to managers and accountants.

When we come to the section dealing with cost allocation, the peculiar nature of the chemical industry becomes apparent. Yields, which play so vital a part in the chemical factory costs, are not a factor in engineering, and so do not come within the scope of this book, but much useful information will be gleaned from the section on cost allocation, though the succeeding sections on standing orders, departmental or intermediate process accounts, and stock production account will be of limited value or interest to trades other than engineering. The section on oncost or expenses, as we prefer the term, is, on the other hand, of importance to all concerned. The fact that interest on capital and depreciation is a logical part of expenses is emphasised as it should be. Here again, however, the chemical manufacturer will have to apply the information to his own particular needs. To mention one instance, the amount and value of steam used in chemical operations is a considerable part of the expense, but finds no mention or application as applied to engineering costs.

The chapter on works routine—specimen forms—gives a mass of information—150 pages—in the nature of forms which are, however, of little interest to those not engaged in engineering, though useful for the purpose of reference.

Looking at the book as a whole, the impression forced upon the chemical manufacturer, and probably upon all but those engaged in the engineering trade, is that it contains an immense amount of information; that parts of it will prove at once of use to those in other than the engineering industry, and that to those who have the time and patience to read it through carefully there are many pages which, although they deal directly with engineering, will give food for thought and may perhaps give rise to ideas in the particular industry in which the reader is engaged.

The book is well printed on good paper (medium 8vo) and full cloth bound. It is published at the not extravagant price, at the present time, of 45s. net.

H. A. D. Jowett.

A Research on the Eucalypts and their Essential Oils. *By* Richard T. Baker *and* Henry G. Smith. *Second edition. Pp.* xv.+471. *Published by authority of the Government of the State of New South Wales, Sydney,* 1920.

Since the time of Baron von Mueller the systematic study of the Eucalypts has been almost entirely in the hands of Baker and Smith. These authorities have departed from purely orthodox methods in classification and have founded species on a system depending not only on morphological characters, but have called to their aid, *inter alia*, the chemical properties of the products of the trees. The system that has been adopted appears to have worked out very successfully.

In the volume under review, which is enriched with numerous beautiful illustrations, the whole of the important Eucalypts are fully described. Information is given concerning the botanical characters of the tree, its habitat, the character of its timber, and a full account of its essential oil.

A special chapter is devoted to a description of the principal constituents found in the Eucalyptus oils, including cineol, geraniol, the terpineols, piperitol, eudesmol, cuminal, aromadendral, and cryptal. A critical survey of the methods for the determination of cineol in eucalyptus oils is included, but the *ortho*-cresol method has, unfortunately, been published in this country just too late to be included in this survey. The authors conclude:—(1) That an accurate method for determining the amount of cineol in eucalyptus oils under all conditions has yet to be discovered; (2) that no one present method is applicable in all cases; (3) that arsenic acid is less advantageous for the purpose than phosphoric acid; (4) that the use of petroleum ether in connexion with phosphoric acid is an advantage if the process be carried out in the manner suggested by the authors.

Among other conclusions they agree with most English chemists that the resorcinol method is only of use with certain types of oil. It is stated that eudesmol occurs in both the liquid and the crystalline conditions, "although the line of demarcation separating them is evidently slight." The authors consider that eudesmol changes its character from crystalline to liquid, and *vice versa*. The explanations of this do not appear to be very satisfactory, and it is probable that further research may prove the existence of isomeric eudesmols, each of constant characters and existing in varying proportions naturally, so that superfusion and similar phenomena may be in question.

Cryptal is a new aldehyde of some interest, and was obtained from two different specimens as a crystalline semicarbazone, melting at 180° C.; there appears to be no doubt of its chemical individuality. Piperitone, the "peppermint" ketone discovered by Smith, is another very interesting constituent of certain Eucalyptus oils, and interesting speculations as to its constitution are made. It is possible that thymol, which results from the oxidation of piperitone by means of ferric chloride, may eventually be prepared in this way on a commercial scale.

The work is very free from errors, and reflects great credit on all concerned in its production.

Ernest J. Parry.

The Technical Examination of Crude Petroleum, Petroleum Products, and Natural Gas. *By* W. Allen Hamor *and* F. Warde Padgett. *Pp.* x.+573. *(New York: McGraw-Hill Book Co., Inc.* 1920.) *Price* 30*s. net.*

This work, primarily written for American students of petroleum technology, will prove of service to all those interested in the examination of petroleum products. The authors have attempted, with success, to compress into a small space the latest physical and chemical methods considered essential for the evaluation of crude petroleum and its derivatives. In order to do this other well-known text-books on the subject have been widely quoted, and the authors have not failed, where they have considered it expedient, to cut out details and satisfy all requirements by referring to the source where such details can be found. Unlike inorganic analysis, the analysis of petroleum bodies depends largely upon empirical methods, carried out according to standard methods in order to obtain comparative results. In such cases the authors have adhered to American methods and have chiefly described those prescribed by the American Society for Testing Materials and the United States Bureau of Standards. For this reason the Redwood viscosimeter is mentioned but not described. The multiplicity of methods now used for reaching the same objective only emphasises the urgent necessity for the early international standardisation of methods in order to save time and prevent confusion.

In addition to chapters on the examination of crude petroleum, illuminating oils, lubricating oils and greases, and bituminous road materials there are valuable chapters on the examination of other petroleum products, the sampling of petroleum oils, the evaluation of oil shales, laboratory methods for benzol-recovery plant operations, and the examination of natural gas. In view of the increasing im-

portance of benzol and the world-wide interest now taken in oil shale, the inclusion of these two chapters adds to the value of the volume. For the latest information on the "Laboratory Testing of Oil Shale for Oil and Ammonia Yield," the paper by Lawson Lomax and Remfry, in the *Journal* of the Institution of Petroleum Technologists, Vol. 7, Jan., 1921, should be consulted.

The descriptive matter in the book occupies circa 300 pages, and the remaining 272 pages are closely packed with an exhaustive appendix containing in compact form chemical and physical data and many valuable specifications for the reference of the refinery chemist, petroleum engineer, and gas engineer. The authors have not failed to give consideration to that very important item in a book of reference—the index—and to emphasise their appreciation of this feature they quote the following from Horace Binney:—"The best book in the world would owe the most to a good index, and the worst book, if it had but a single good thought in it, might be kept alive by it."

The thought underlying the structure of this work is so good that its continued appearance as a standard handbook on the subject in its present form is to be expected. There is no doubt that the analyst or petroleum technologist in possession of this book has at hand a reliable work of reference, and with the methods described and those referred to is in a position to carry out all the essential tests on petroleum products.

M. B. BLACKLER.

OBITUARY.

J. W. LEITCH.

John Walker Leitch, who died on April 10, was born at Paisley, in 1865, and was educated at the Royal College of Science, South Kensington, and at the University of Glasgow, where he took the B.Sc. degree. In 1887 he came to Milnsbridge, near Huddersfield, as secretary and chief chemist to Messrs. Dan Dawson Bros., Ltd., one of the pioneers in the colour-making industry. In 1890 he started business on his own account and shortly afterwards established the present firm of Messrs. John W. Leitch and Co. at Milnsbridge Chemical Works. Throughout his career Leitch devoted himself to the manufacture of coal-tar products. Specialising on the nitro- and amino-derivatives of benzene and toluene, he established a standard of excellence in the intermediates and colours which he manufactured that was not bettered even by the Germans. Not only have the effects of his work been felt in the colour industry, but also in the heavy chemical trade and in the field of explosives manufacture, where his intimate knowledge of the aromatic nitro-compounds proved of great value. Leitch held numerous patents covering improvements to processes and to plant, particularly in respect of the recovery of sulphuric acid from waste acid, plants to his specification having been installed in numerous works. Years before the war he developed the manufacture of dinitrotoluene for dye-making, incidentally obtaining TNT, and extended the production of the latter in the early period of the war, producing an almost perfectly pure product. He gave unstintingly of his energy to assist the Authorities in the manufacture of explosives, and as the result of his exertions on war work he suffered a very serious breakdown in health in 1917, which lasted for twelve months, and from the effects of which he never completely recovered.

Leitch was first president of the Chemical Employers' Federation (Yorkshire Section), an active member of the Association of British Chemical Manufacturers, and was keenly interested in the improvement of facilities for higher technical instruction in Huddersfield, where he was a member of the Technical College Coal-Tar Extension Committee. He was chairman of the Board of Trade Commission that visited the German colour works in the occupied territory, and reported on their condition shortly after the armistice was signed. A member of this Society since 1894, he was until recently a regular attendant at the Society's annual gatherings.

AMMONIA OXIDATION AT HÖCHST

J. R. PARTINGTON.

The ammonia oxidation plant of the Höchst Farbwerke (vormals Meister, Lucius und Brüning) is situated at Höchst, on the right bank of the Main, about 10 miles from Mainz. It is about two miles from the works of the Griesheim-Elektron Co., with which, however, it has no connexion. During the war an amalgamation with the Badische interests took place, synthetic ammonia from Oppau being supplied to Höchst for oxidation (*cf.* J., 1921, 99 R). There was before the war an oxidation plant at Höchst, comprising 37 converters fitted with circular platinum gauzes about 7·2 in. diameter, contained in vessels similar to those used for contact sulphuric acid. The efficiency of this plant, which produced about 54,000 tons of nitric acid per annum, was not above 80 per cent., and a new plant, completed in February, 1919, was erected in its place at a cost of about £1,000,000. This plant has a capacity of 24,000 tons of ammonia, or 140,000 tons of nitric acid, per annum.

In addition to synthetic ammonia, arriving as 25—27 per cent. liquor from Oppau, gas liquor ammonia (20 per cent. NH_3), and cyanamide ammonia liquor (22—27 per cent.) from Knapsack (*cf.* J., 1919, 303 R) were received, the liquor being stored in four overhead spherical steel tanks, each of 264,200 gallons capacity. The liquor was rectified in four stills, one spare, of the Savalle type with 15 effects, each with a capacity of 20 tons of ammonia daily. The gas not used for oxidation was absorbed in a plate tower 30—40 ft. high. Ammonia from gas liquor was scrubbed with caustic soda solution of 48—53° Tw. and then passed through charcoal purifiers in the usual way to remove sulphur compounds. The ammonia gas from the stills was freed from moisture by refrigeration with ice-cold water; the presence of moisture caused scaling of the iron pipes and was also believed to be prejudicial to the conversion, although there is no evidence of this.

The ammonia gas and air were metered through Venturi meters and driven by ten 55 kw. centrifugal blowers to the filters and converters. The mixture contained 12·5 per cent. by volume of ammonia, regulated within narrow limits. The ammonia supply pipe was 6 in. diameter and the air pipe 18 in. diameter. The air was filtered through cloths in a wooden box and the mixed gas was carefully filtered from dust and ammonium salt fumes through eight layers of linen cloth in chambers 9 ft. by 5 ft.

The gas passed under 6 in. water pressure through two central mains in the converter house, from which it was diverted to the 224 converters, each provided with a circular platinum gauze catalyst of 20 in. diameter, or 2·12 sq. ft. cross section. The maximum output of each converter was 1·5 tons of nitric acid per 24 hours, the efficiency of oxidation being 89 per cent. The efficiency from ammonia to dilute acid (including the efficiency of the absorption plant) was 87 per cent.; that from ammonia to strong acid (including the concentrating plant) was 84 per cent. The body of the converter (Fig. 1) consists of cast iron, in four sections with flanges. The two middle sections were 18 in. and 12 in. high, and supported the catalyst between them; the conical top and bottom pieces were each 3 ft. 6 in. high. The top cone was lined with sheet nickel to protect it from the hot gas. The catalyst, clamped between asbestos rings, was started by heating to redness by a hydrogen or coal-gas flame inserted below it through a lighting hole shown in the figure.

The exact construction of the catalyst has been differently stated. It has been asserted that it consists of two, or three, or four platinum gauzes, 20 in. diameter, of 0·06 mm. wire with 80 meshes to the linear inch. The gauzes are possibly spot-welded and are supported on a grid of ten stout platinum wires, 1 mm. diameter, spaced at 10 cm. distance. The total weight of platinum in the catalyst has been stated as 333 grams, which does not agree very well with the details of construction, but is probably approximately correct.

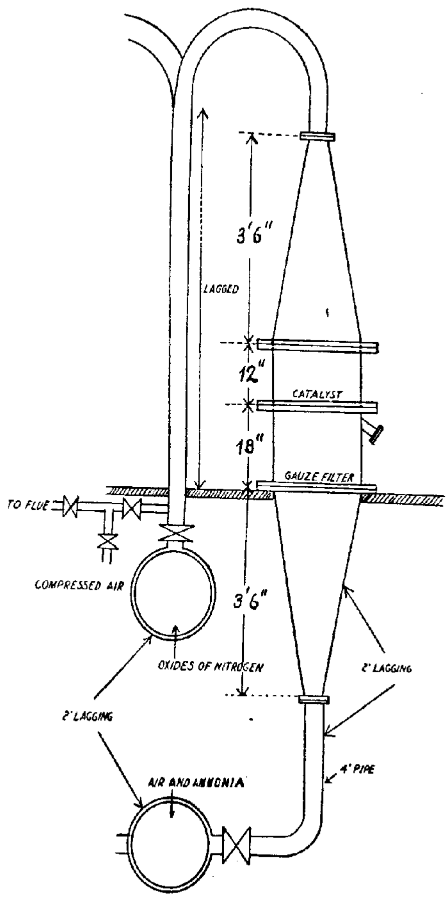

FIG. 1.

The converters were arranged in two sets of seven or eight on each side of separate inlet and outlet mains, the latter 1 ft. in diameter and connected with the converters by 4 in. pipes, lagged with diatomite brick shaped to fit, cemented and wired. The upper bend pipe of the converter was not lagged, so as to allow for expansion. Before entering the converters the gas passed from a common main to a vertical, lagged, multitubular pre-heater, 15 ft. by 5 ft. external dimensions, in which it was heated by steam. The purpose of this was to prevent condensation of acid from the hot gases coming from the converter when these were passed through the heat-exchanger which followed. In this, which was identical in dimensions with the pre-heater, the warmed gas passed in counter-current to the gas from the converters, and left at 200° C. Two heaters so arranged served 14 converters. The temperature of the catalyst was about 800° C.; the gas left the converter at 650—700° C. In starting the converters extra air could be added and the only

partly converted exit gas by-passed to a chimney until the gauze was activated. Gate valves were used, with a slight air pressure on the side of the valve not in contact with the gases to prevent leakage. In 56 of the latest type of converters the gas was passed by a lagged 3 ft. main through two tubular boilers, leaving these at 270° C. to the heat exchanger. In this way four tons of water was evaporated per hour and the steam was used for warming the gas, as described above. From one to three men only are necessary to attend to all the converters.

The gases containing nitric oxide and steam coming from the converters were passed through eight cast-iron mains 18 in. diameter, supported on three ferro-concrete bridges, to four rows of eight absorption towers. Each row of towers was provided with twelve intensive coolers of special design, *i.e.*, 48 coolers in all. These coolers (Fig. 2) were of aluminium, with an annular space between the outer wall and an inner vessel, the gas entering above through a 4-in. inlet, dividing into four 2-in. pipes leading to an annular space between the walls. The gas and condensate left through a 4-in. outlet below. The coolers are 5 ft. high and 2 ft. 6 in. diameter. In these, on account of the rapidity with which the gas passed through, practically no acid was condensed, but only water. The condensate was put down the fifth absorption tower. The gas left the set of 4 coolers at 30° C. through 4 pottery mains 1 ft. diameter, joining to a single brick chamber at the base of each set of eight towers attached to 56 converters. Secondary air was admitted at this point (not before the coolers).

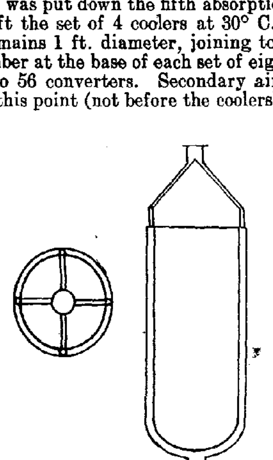

FIG. 2.

The towers are 41 ft. high and 21 ft. diameter internally. The walls comprise three layers of brickwork, the outer layer of bricks 6 in. by 4 in., set in a mixture of sodium silicate and kieselguhr. The top of the tower is slightly domed, and there is a central partition in each tower, the gas passing up one side and down the other, and then going to the next tower through a brick channel at the base. The towers are packed with stoneware rings. The total internal volume of all the towers is 35,320 cb. ft., which amounts to only 81 cb. ft. per lb. NO, absorbed per minute as compared with 350 cb. ft. calculated by the formula proposed by Dr. Parker and the writer (*cf.* J., 1919, 75 T), or 1500 cb. ft. as used at the French works at Bassens when we saw it in 1918. The reason why this small tower capacity is effective is clear when it is remembered that at Höchst no less than 25 per cent. of the oxides was absorbed as nitrate by saturated sodium carbonate solution fed to the last two towers. The liquor in the first of these towers is allowed to become acid, so that the nitrite is converted into nitrate, whilst that in the second is kept alkaline, to absorb the oxides of nitrogen driven out of the first when conversion into nitrate occurs (see B.P. 129,699/1919; Partington and Rideal). The solution of nitrate was evaporated by the waste heat of the converters. The remaining towers were fed with water for the production of nitric acid. The efficiency of absorption plant was 97 per cent. Each tower is stated to have cost 40,000 marks. Acid of 50 per cent. strength was obtained from the first tower of the series, the liquid being circulated in the towers by 8 in. chrome steel centrifugal pumps each fed by a 3—4 in. pottery main and delivering through a silicon-iron pipe of the same diameter to the top of the tower, two delivery pipes being used to each tower. The metal pipes were coned and fitted in the same way as the pottery pipes. Acid distribution was effected at the top of the tower by a revolving ribbed disc, turned by a gear shaft at 80 revs. per min.

The acid from the towers was passed to the coolers, consisting of S-pipes of silicon-iron cooled externally with water. There were also intercoolers between each pair of towers except the last, and the temperature was kept as low as possible, 25° C. in winter and 40° C. in summer. The fact that the dilute acid towers would probably work slightly better if warm (see Partington and Parker, *loc. cit.*) does not seem to have been appreciated. In summer ice-water was used in the coolers. Large stoneware receivers were placed above the coolers to serve as acid reservoirs. The circulation in each tower was 110 gallons per min.; the loss of acid in the whole system did not exceed 2 per cent.

Twelve stock tanks of brickwork, each holding 1412 cb. ft., received the tower acid from the receivers at the base of the towers, through tapered pottery pipes. No fan was used with the towers.

The tower acid was concentrated by mixing 7 parts of 50 per cent. tower acid with 1 part of sulphuric acid, in five mixing vessels with mechanical stirrers and then denitrating. About 42,000 tons of sulphuric acid was used per month, but practically all was recovered. (In France 2·5 to 3 parts of sulphuric acid only were used, but the nitric acid obtained was less concentrated—85 per cent. strength—than that obtained at Höchst. The nitric acid was recovered partly in two rows of nine silicon-iron towers, 4 ft. diameter and 25 ft. high, and partly in stone towers, with cast-iron pipe jackets, 35 ft. high and 3 ft. 6 in. external diameter, the walls being 9 in. thick. Steam at 150° C. was introduced at the base by a 1 in. lead pipe just above the exit for the denitrated acid. The nitric acid vapour from the top of the denitrator passed to a cooler of S-shaped silicon-iron pipes. The acid to be denitrated entered half-way down the cooler and acid from stock was sent down the upper part to assist condensation. Oxides of nitrogen were removed from the nitric acid by a current of air and recovered in 20 absorption towers. The completely denitrated sulphuric acid was cooled in a water-cooled cast-iron cooler and collected in a large lead-lined tank of artificial stone. It contained about 70 per cent. sulphuric acid and was reconcentrated in a Kessler apparatus or in a modified Pauling apparatus (*cf.* J., 1920, 656 A). The latter was said to be very efficient. (In French practice a denitrating column 20 ft. high and 18 in. internal diameter produced 6 to 8 tons of nitric acid per day with an overall yield of 85 to 87 per cent. on the ammonia burnt in the Ostwald type catalysts. The consumption of fuel in reconcentrating the sulphuric acid was 15 to 20 per cent. of the weight of nitric acid produced.)

It is of interest to compare the mode of operation at Höchst, representing the latest German practice, with the indications obtained by experimental work in England, unfortunately never translated into technical practice. The resemblance is striking. In the following comparison the experiments carried

out by the writer and his colleagues for the Munitions Inventions Department are referred to, many of which have not been published. The separation of water from the converter gas by rapid cooling was the subject of B.P. 131,942/1918 (Rideal and Partington). The object of this procedure, which is combined with the addition of secondary air *after* the coolers, is to keep the gas as concentrated as possible in the oxidation and absorption towers. It is clear from the equation $4NH_3+5O_2=4NO+6H_2O$, that the uncooled converter gas contains nitric oxide and steam in the ratio 2 to 3 by volume, so that if the steam is removed a considerable concentration in oxides of nitrogen results.

The dimension of the platinum wire and the mesh of the gauze are also those found most suitable by the writer, and if the use of two gauzes at Höchst is the correct description this is also in agreement with the type of catalyst recommended in the official publication, "Ammonia Oxidation applied to Vitriol Chamber Plants," M.I.D., Stationery Office, 1919. The use of alkali to finish the absorption was carried out exactly in the manner specified in B.P. 129,699/1919 (Rideal and Partington); it has been shown that this effected a considerable economy of tower space. The use of sulphuric acid as an absorbent, which was tried at Leverkusen and found unsatisfactory, was also the subject of a long series of experiments (unpublished) by the writer and Dr. Parker, who decided that it was not an efficient method of absorption.

It may fairly be said that laboratory workers in England and Germany seem to have been led to the same conclusions, but whereas the German technologists translated the results into plant the English work finished in the research laboratory.

YEAST GROWTH.

LEWIS EYNON.

The growth of yeast, first closely investigated by Pasteur, has since been the subject of much research and controversy. In suitable media, such as malt wort, the growth is characterised by three phases, viz.:—(1) the quiescent, or lag phase, observed when old yeast cultures are introduced into fresh wort, (2) the logarithmic phase or period of unrestricted growth, and (3) the phase of retarded growth due to exhaustion of oxygen or food, or to accumulation of carbon dioxide and other toxic substances. The yeast crop finally obtained is obviously dependent on the various factors which retard growth. It is shown by Dr. A. Slator (Chem. Soc. Trans., 1921, 119, 115) that if yeast is grown under such conditions that only one of these factors comes into play, it is possible to determine the influence of the individual factors on the yeast crop. Thus, provided the ratio of the constant of growth, K, to the fermentative activity of the yeast, F, is constant, the yeast crop should be approximately proportional to the initial concentration of the sugar when this constituent of the medium is made the limiting factor (*cf.* J., 1919, 392 R). The proportionality was tested with a wild yeast of the *S. ellipsoideus* type grown in a fermented wort that had been freed from alcohol and treated with small quantities of glucose; direct proportionality between yeast crop and initial glucose concentration was found to hold up to about 1 per cent. of sugar, 3900×10^6 cells being produced per 1 gram of sugar fermented. It is further found that with sugar as the factor controlling growth the yeast crop (*S. cerevisiæ* grown in wort) is practically independent of the fermentation temperature between 10° and 25° C., as should be the case since the temperature coefficients of K and F do not differ greatly. The influence of the amount of seeding on the yeast crop is *nil* provided that actively growing cells are used for seeding, *i.e.*, the crop is the sum of the seeding and the growth, the latter being constant. The retarding influence on growth of carbon dioxide remaining dissolved in the wort is very marked and is not attributable merely to exclusion of oxygen. With regard to the influence of oxygen on yeast growth, Slator has attempted to verify the opinion that malt wort contains a certain amount of combined oxygen available for yeast growth (*cf.* J., 1919, 392 R) by estimating yeast crops under such conditions that the oxygen-containing substance would become the limiting factor determining the crop. His experiments, however, do not bear out this opinion, but suggest that there are two different modes of growth of yeast, one of which is illustrated by the initial stages of growth in malt wort, and the other by growth in lactose-yeast-water. In the former, oxygen (either free, combined, or absorbed by the yeast) plays no part save that in the free state it slightly retards growth, carbon dioxide retards growth, and the energy necessary for growth is obtained from the fermentation of the sugar. In the latter mode of growth, which is unaccompanied by alcoholic fermentation, free oxygen is essential, carbon dioxide in large amount retards growth, and the energy necessary for growth is obtained through some oxidation reaction carried out by the yeast.

As Slator observes, there is some similarity between the views now advanced by himself and those expressed by Pasteur with regard to the influence of oxygen on yeast growth. Thus, Pasteur observed *Études sur la Bière*) that yeast can live and multiply in absence of oxygen, although under these conditions the amount of yeast produced is very small by comparison with the amount of sugar fermented. Thus, in one experiment in which fermentation was effected with exclusion of air the ratio of the weight of (dried) yeast to that of sugar (sucrose) fermented was 1:89, whilst in another experiment in which a more mature yeast culture was used for seeding, the ratio was 1:176, and the yeast crop showed abundant evidence of involution. Pasteur inferred that in order to grow in absence of oxygen, the yeast cells must be young and vigorous and still under the influence of the vital activity produced by the free oxygen which has aided their formation, and which perhaps they have temporarily accumulated; very old yeast cultures were found to remain quite inert in a medium from which free oxygen was excluded. In further experiments, Pasteur showed that the ratio of yeast produced to sugar fermented or consumed is greatly increased by the presence of air, this ratio being as high as 1:4 under extremely favourable conditions of air access. Under such conditions a considerable part of the carbon dioxide evolved is produced, not by fermentation, but by oxidation resulting from assimilation of atmospheric oxygen, *i.e.*, to this extent the yeast behaves like an aerobic organism. Pasteur subsequently showed that with air access yeast can multiply in a solution of lactose in yeast-water without producing any fermentation whatever, thus proving that yeast is capable of a strictly aerobic existence. He concluded that the fermentative power of yeast can vary widely between limits which are determined by a maximum and a minimum access of oxygen. With maximum access of oxygen yeast ceases to be a ferment, *i.e.*, the ratio of the yeast crop to the weight of sugar consumed is of the same order as for aerobic organisms, such as moulds. This mode of life corresponds with the second mode of growth (growth in lactose-yeast-water in presence of oxygen) outlined by Slator. With minimum access of oxygen yeast still grows, though much less actively than in presence of more oxygen, and its capacity for fermenting sugar is greatest. This mode of life (*"la vie sans air"*)

corresponds to some extent with the first mode of growth (initial stages of growth in malt wort) outlined by Slator, but Pasteur's view differs from that of Slator in that the former assigned an all-important rôle to the oxygen with which the yeast has previously been in contact. Slator considers that the increase in yeast crop obtained by aerating fermenting wort is due, not to the influence of oxygen, but to displacement of carbon dioxide, and he suggests that the larger yeast crop obtained from wort saturated with air compared with that from wort containing no air may be due to lessened supersaturation of the wort with carbon dioxide.

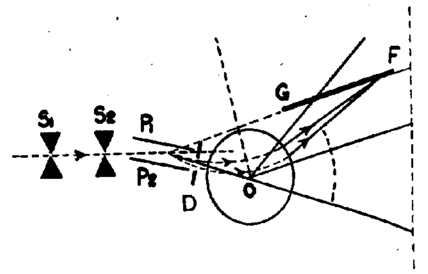
With regard to the two modes of growth, Slator states that "the factors determining which mode of growth takes place when both are possible have not yet been completely investigated." It is clear, from Pasteur's writings (*loc. cit.*, p. 252), that he considered that yeast can grow in both modes simultaneously, *i.e.*, as a fermenting organism and as an aerobe, and that the predominance of its fermentative or aerobic character depends on the amount of air at its disposal.

MASS SPECTRA AND ATOMIC WEIGHTS.

The atomic theory of matter put forward by Dalton in 1803 has remained one of the articles of faith of chemists until very recent years. Even now, only in one of the five main postulates of the theory has a flaw been detected. Dr. F. W. Aston, in a lecture delivered recently before the Chemical Society, reviewed the evidence, largely the outcome of his own work, which has undermined the chemist's and physicist's confidence in the postulate that "atoms of the same element are similar to one another and equal in weight."

The phenomena of radio-activity led to the conclusion that varieties of certain transformation products, more especially varieties of lead, were possible, which, while possessing chemical properties identical in every respect, nevertheless differed in atomic weight. This conclusion was abundantly verified by determinations of the atomic weight of specimens of lead derived from various sources, and the name "isotopes" was suggested by Soddy for such elements which, although exhibiting different atomic weights, yet occupy the same position in the Periodic Table. Moseley's work showed that the chemical properties of an element depend not on its atomic weight, but on its atomic number, which connotes the number of units of positive electricity on the atomic nucleus. Thus the atomic number of hydrogen is 1, of helium 2, of lithium 3, and so on. J. J. Thomson, by the method of positive-ray analysis, obtained evidence that neon, of which the accepted atomic weight was 20·20, was really a mixture of isotopes of atomic weights 20 and 22. The evidence was not as sufficiently conclusive as desired, and Aston undertook further investigations, using Thomson's method, but varying the procedure in order to obtain greater accuracy.

The apparatus employed is illustrated in the accompanying figure.* Positive rays proceeding from the perforated cathode of a cathode-discharge tube are sorted out into a thin strip by means of two parallel slits, S_1S_2, and are then spread into an electric spectrum by means of the charged plates, P_1P_2. A portion of this spectrum is isolated by the diaphragm D and passed between the circular poles of a powerful electromagnet O, whereby the rays are bent back through an angle more than twice the initial deflection. As a result, rays constituted of corpuscles having a constant mass converge to a focus, and a spectrum dependent upon mass alone may be photographed on a plate placed at GF.



The measurements of mass made in this way are relative to lines of known masses, thus C, 12; CH, 13; CH_2, 14; CH_3, 15; CH_4 or O, 16; CO_2, 44. When neon was employed in the tubes, spectrum lines corresponding to masses 10, 11, 20 and 22 were obtained. The first pair are what are termed second order lines, and arise from the presence of rays carrying a double charge. The relative intensities of the remaining lines indicated that neon was a mixture of an isotope of mass 20 with 10 per cent. of an isotope of mass 22, giving an average atomic weight of 20·20 in accordance with the accepted figure. The method has been applied to a number of electronegative elements, and lately it has been found possible to extend the method to the investigation of electropositive elements. The results obtained are summarised below:—

Table of Elements and Isotopes.

Element.	Atomic number.	Atomic weight.	Minimum number of isotopes.	Masses of isotopes in order of intensity.
H	1	1·008	1	1·008
He	2	3·99	1	4
B	5	10·9	2	11, 10
C	6	12·00	1	12
N	7	14·01	1	14
O	8	16·00	1	16
F	9	19·00	1	19
Ne	10	20·20	2	20, 22, (21)
Si	14	28·3	2	28, 29, (30)
P	15	31·04	1	31
S	16	32·06	1	32
Cl	17	35·46	2	35, 37, (39)
A	18	39·88	(2)	40, (36)
As	33	74·96	1	75
Br	35	79·92	2	79, 81
Kr	36	82·92	6	84, 86, 82, 83, 80, 78
I	53	126·92	1	127
X	54	130·2	5, (7)	129, 132, 131, 134, 136 (128, 130?)
Hg	80	200·6	(6)	(197-200), 202, 204
Li	3	6·94	—	6, 7
Na	11	23·00	1	23
K	19	39·10	2	39, 41
Rb	37	85·45	2	85, 87
Cs	55	132·81	1 (?)	133

The numbers in brackets are provisional. The results indicate that within an accuracy of 1 in 1000, *the weights of the atoms of all the elements measured, except that of hydrogen, are whole numbers*, thus re-establishing Prout's hypothesis, but with the modification that the primordial atoms are of two kinds, viz., the electron, or atom of negative electricity, and proton, the atom of positive electricity. A neutral atom of an element of atomic number N has a nucleus consisting of K+N protons and K electrons, and round this are set N electrons. An atom of atomic weight m is turned into one of atomic weight m+1 by the addition of a proton plus

* Reproduced, by permission, from the *Philosophical Magazine*.

an electron. If both enter the nucleus, the atomic number is unaltered, and an isotope of the original atom results. If the proton alone enters the nucleus, an atom of the next higher atomic number results. If both new configurations are possible, elements of the same atomic weight but with different chemical properties result. Such elements are called "isobares." Their occurrence among radioactive elements is known. The hydrogen atom is unique; it is the only atom in which the nucleus is not composed of a number of protons packed very closely together. When four protons are packed closely with two electrons to form the helium nucleus, theory indicates a reduction of the effective mass, so that the helium nucleus will have a weight somewhat less than four times that of hydrogen. The lecturer concluded with the remark:—"Though as a chemist I view with some dismay the possibility of eighteen different mercuric chlorides, as a physicist, it is a great relief to find that Nature employs at least approximately standard bricks in her operations of element building."

SOCIETY OF CHEMICAL INDUSTRY.

NEWS FROM THE SECTIONS.

SHAWINIGAN FALLS.

A dinner was held by the Shawinigan Falls Section at the Cascade Inn, Shawinigan Falls, on April 12, and was attended by about forty members.

After the customary toast to the King, the chairman, Dr. F. W. Skirrow, introduced Mr. V. C. Bartram, of the Canadian Electro-Products Co., who gave a very interesting address on the situation in Europe. Mr. Bartram passed a considerable portion of the year 1920 travelling in England, Holland, Belgium, France, Italy, and Switzerland, and he spent a month in Germany visiting most of the larger chemical centres. He was much impressed by the difference between the commercial conditions prevailing in Germany and those in England. There seemed to be absolutely no unemployment in Germany, and most industries were working at full capacity, especially those industries which were able to obtain their raw materials in the country. In many instances, however, plants were working at full capacity on raw materials obtained through outside interests, the owners of the materials being charged so much per kilogram or metre for the work done upon them. In this way employment was being maintained in Germany and unemployment in surrounding countries. Unless steps were taken to protect industries in Allied and neighbouring countries, it would, in Mr. Bartram's opinion, be very difficult for their manufacturers to compete with German manufacturers for some considerable period. Mr. Bartram found the German people very polite, and anxious to impress one with the extent of their wealth. It would appear as if the Germans, not knowing the exact steps which are going to be taken to collect the indemnity, are very keen to dispose of such wealth which they have retained in Germany to their own personal advantage, *i.e.*, to get the most enjoyment out of the money while they have it. Mr. Bartram is of the opinion that by proper control of industry and increased taxation, the Germans could well afford to pay the indemnity demanded by the Allies, and that at the present time they are really prosperous, although very short of some of the real necessities of life; however, they seemed to be reconciled to getting along with a minimum of luxury and without many of the things we here consider necessities.

Owing chiefly to the enormous inflation of money, a traveller in Germany gains the impression that the country is immensely rich, and that there are only two classes in Germany to-day, the extremely rich and the extremely poor. The inflation of money has been much greater than the increase in prices, and many persons who had property to dispose of have sold it and become very rich almost without effort. It would appear that Germany can only hold her present advantages in many of the world's markets she is now dominating until such time as the German populace tires of living under the conditions existing there to-day. There is no doubt that the Germans realise they have been beaten, but many feel that by sticking closely to work and doing everything possible to maintain production on an economic basis they are dealing a severe blow to Allied interests, and in this way getting back some of their own. It would hardly seem possible that the German populace can long continue to maintain their present standard of living, and doubtless the trade situation will rapidly be forced down to a level at which Germany will cease to enjoy her present advantages. The import duties adopted by other Governments to counteract the advantages Germany now enjoys through exchange should improve the situation in the rest of the world and particularly within the Empire.

Mr. Vinet, of the Shawinigan Water and Power Co., then made a few remarks on his visit to Germany with the Allied Army of Occupation in 1919.

MANCHESTER.

About 70 members attended the last meeting of the Session, which was held at the Textile Institute on May 6, Mr. John Allan presiding.

In a short communication on "Woad," Mr. J. Hübner stated that the prohibition of the import of dyes could be traced back at least to the 15th century, for he had found in the British Museum a special licence granted and signed by Henry VII. for the importation of 230 tons of woad from France. Although woad grew in this country from very early times, it was not cultivated here until the 15th century. When serious attempts were made to cultivate it, its importation was prohibited. Many of these attempts failed because continental growers, although willing to supply seeds, destroyed their germinating power by boiling them in water or smoking them in chimneys.

Mr. W. H. H. Norris read a paper on "Methods for the Complete Recovery of Nitre Cake," in which he described a process which had been used on a manufacturing scale. This consists, briefly, in digesting the cake with hot process liquor and so precipitating all the salt cake in a pure state, leaving the acid in solution. The mixture is filtered and washed in centrifugals, and the resulting acid liquor is used for ammonia absorption. The ammonium sulphate liquor is evaporated until a definite density is reached, and the process liquor is run back to the digester to neutralise the acidity of a fresh charge of nitre cake.

A new process for recovering sodium sulphate and a strongly acid liquor was also described, which involves running off the residue from the retort and pelleting it in a digester in presence of liquors of regulated composition. A second treatment of the liquor in the same vessel produces anhydrous sodium sulphate (96 per cent.). For transport, the acid liquor of 60 per cent. acidity may be diluted to about 25 per cent. acidity without risk of crystallisation taking place when cooled to 10° C.

Mr. R. Curtis, in a paper on "Works Accounts from the Chemist's Point of View," referred to the excellent work carried out during the war by the Department of Explosives Supply, and illustrated the type of system required by the works chemist with particulars of the method used at H.M. Factory, Avonmouth. The works chemist needs a detailed analysis of all manufacturing costs which must be made available at the earliest possible

moment. Costing information supplied two or three months after the expenditure has been incurred is of little value.

ANNUAL MEETING, 1921.

CANADIAN ASBESTOS.

The asbestos-mining companies of Quebec have extended a cordial invitation to the members of the Society to visit their mines and mills on the occasion of the Annual Meeting in Montreal.

Although 85 per cent. of the world's asbestos is produced in Canada, it all comes from a comparatively small district about three hours' journey from Montreal. There are fourteen principal producers located at Coleraine, Black Lake, Thetford, East Broughton, and Danville.

The mining and milling of asbestos consists of quarrying proper, and the "cobbing" or separation of the fibre from the rock.

The first operation in opening a quarry is the removal of the surface soil, usually from 5 to 25 feet deep, for which steam shovels are employed. The exposed rock is drilled by hand, machine, or electric percussion-drills. This is followed by blasting with dynamite, every pound of which brings down about five tons of rock. Hand-cobbing separates the crude material into three grades:—(a) The long asbestos fibres and pieces of rock containing them; (b) the milling material or rock containing the shorter fibres; and (c) barren rock which goes direct to the dump.

The material specified in (a) is sent direct to the cobbing sheds, where the fibres are separated into different grades both by hand and machinery. The rock containing the shorter fibres is crushed and the asbestos separated from the waste by exhaust fans. The asbestos is now ready for the market, and is classed into two grades, termed respectively the "crude" and the "fibre." The crude is divided into two grades, No. 1 having fibres over 0·5 in. long, and No. 2 containing fibre under 0·5 in. These grades are used for asbestos cloth, pipe-covering, and other articles of which asbestos is the principal constituent. The material of shorter fibre is used in other manufactures, chiefly as a filler.

The production of asbestos has grown from 1400 tons, valued at £30,000, in 1885, to 120,000 tons, valued at £2,250,000, in 1919.

MEETINGS OF OTHER SOCIETIES.

THE INSTITUTE OF METALS.

On May 4 Prof. T. Turner, of Birmingham University, delivered the Eleventh May Lecture, on "The Casting of Metals." Sir George Goodwin, president of the Institute, was in the chair.

In opening, Prof. Turner referred to the castings of antiquity, mainly bronze, silver, and gold, many of which were of high quality and great beauty, but there was no reason to believe that the achievements of the past could not be equalled in design and excellence by modern methods, whilst output had been increased enormously and the percentage of wasters reduced. Casting may be defined simply as "the art of filling a given space by means of a molten metal or alloy"; yet it is the exception rather than the rule to obtain a perfect casting. In general, the higher the melting point of the metal or alloy the greater the casting difficulties, partly owing to the condition of the metal, and partly on account of the necessity for obtaining high-class refractories, sands, cores, fuels, etc. A valuable property of metals is their low viscosity in the liquid state; in most cases the viscosity does not exceed appreciably that of water, so that very intricate shapes can be cast. In addition, the surface tension as a rule is high, and coarse-grained-sand moulds can be used since they are not "wetted" by the molten metal or alloy. The latent heat of metals, which governs the rate of solidification, is usually the greater the higher the melting-point, but aluminium is a notable exception, having a very high latent heat. The coefficient of expansion of aluminium is also very high and renders the metal liable to fracture while cooling in the mould. Molten metal, melted in ordinary furnaces, practically always contains in solution gases derived from the atmosphere of the furnace, and these gases may be evolved during solidification in the mould with the formation of blowholes. For most metals and alloys, however, there is a suitable pouring temperature at which the evolution of gas during casting is not excessive. The amount of "superheat" (heating above melting point) which is necessary to obtain sound castings varies greatly with different alloys.

Pure metals, as a general rule, possess the same density whether slowly or quickly cooled. In the case of alloys, especially those in which there is a wide temperature-interval between the liquidus and solidus, slowly cooled castings, such as sand-castings, frequently expand during solidification, and the result of this expansion is reflected in a reduction in the density of the alloy. The work of Prof. Turner and his students, in which the volume changes in a number of typical alloy systems during solidification were investigated, has shown the connexion between the constitution of the alloys and the alteration in volume, and the results can be correlated with the densities of the solid alloys. The lecturer closed with a reference to the causes of failure in casting metals, among which may be mentioned, pouring at an unsuitable temperature, imperfect cores, faults in moulding, cracks, misruns or run-outs, and breakage in handling. The losses from these and other causes are considerable; they usually amount to about 10 per cent. but sometimes to 40 per cent. of the output.

THE IRON AND STEEL INSTITUTE.

The annual meeting was held on May 5 and 6 at the Institution of Civil Engineers under the presidency of Dr. J. E. Stead. After the formal business was concluded, Mr. Harry Brearley read a paper on the welding of steel in relation to the occurrence of pipes, blow-holes, and segregates in ingots. His experiments were designed to ascertain to what extent the surfaces of cavities in ingots were welded up in operations such as forging, rolling, etc. He found that welding was as a rule not perfect, although it was frequently impossible to detect the weld in polished and etched samples. Under the notched-bar impact test, however, splitting frequently occurred along the welded surface when this was longitudinal in the test-piece. This tendency to splitting was greater the tougher the steel, and it was suggested that the quality of a weld could be measured by ascertaining the degree of toughness which must be induced in the steel in order to pull apart the welded surfaces in the ordinary Izod test. Mr. S. H. Fowles presented a paper on the cleaning of blast-furnace gas, and gave a description of the Halberg-Beth dry gas-cleaning plant. He pointed out that waste gas and heat should be used with the maximum efficiency, and that to use the gas under boilers was a barbarous practice. He advocated its use in internal-combustion engines, after careful purification in a suitable cleaning-plant; and he pointed out the defects of existing types of gas-cleaner, whether they were based on the wet process, the dry process, or the electrostatic process. Mr. J. E. Fletcher described graphic methods of representing the composition and melting points of various blast

furnace and cupola slags, with a view to obtaining a clearer understanding of the theory of slags and of their practical utility.

The prevention of hardening cracks in a tungsten tool-steel containing 1·1 per cent. carbon and 0·8 per cent. tungsten was discussed by Mr. S. N. Brayshaw in a very long paper which embodied an enormous amount of experimental work. A series of milling cutters of complicated design was used for his experiments, which sought to correlate the liability to crack with the heat-treatment before and during hardening. A paper by Messrs. K. Honda, T. Matsushita, and S. Idei discussed the cause of quenching cracks. These are attributed to structural differences in the quenched samples; in small samples a core of martensite exerts a large tangential tension on the periphery, which consists largely of austenite; cracks in large samples may be formed as a result of stresses due to the structural differences between the inner and outer portions—pearlite and austenite—just below the A1 point. Mr. J. H. Whiteley described a preliminary investigation on the cupric etching effects produced by phosphorus and oxygen, respectively, in iron. From his results it appears that differences in the phosphorus content of less than 0·02 per cent. in adjacent parts of otherwise pure iron can be readily discovered by means of the cupric reagents; as the difference is increased, at least up to 0·15 per cent., the contrast becomes more and more pronounced. On the other hand, attempts have failed to produce an unequal distribution of oxygen which could be detected by cupric reagents in the same manner as that of phosphorus. Two methods of obtaining an unequal oxygen content were used:—(a) By soaking pure iron in its own oxide at a high temperature and then welding it with the unoxidised material; (b) by reducing highly oxidised iron in hydrogen and then welding it with the original metal at a low temperature. On etching, white resist-lines were formed at the weld junctions when oxygen was present, but these resist-lines were not formed when unoxidised iron was welded in dry hydrogen. Dr. Stead also contributed a paper dealing with the question of the solid solution of oxygen in iron, and from his results it appears that the absorption of oxygen into solid solution by iron can no longer be doubted. When iron, which has been heated in air or oxidising gases and has absorbed oxygen, is supersaturated, the oxide falls out of solution in the form of globules of free oxide. These globules become larger and larger as oxidation proceeds, eventually joining together to form continuous layers. Other globules which appear in iron as the result of gaseous action are sulphide of manganese and possibly protoxide of manganese, though in what form the sulphur enters the iron is not known.

Dr. A. Westgren's paper on "Röntgen Spectrographic Investigations of Iron and Steel" was introduced by Sir William Bragg. The paper is a brief report on the first results obtained by the application of Röntgen spectrographic methods to metallographic problems. The work described verifies Hull's result that iron at ordinary temperatures (α iron) has a cube-centred cubic lattice structure. The same orientation is found at 800° to 830° C., that is, within the so-called β iron interval, from which Dr. Westgren concludes that iron does not undergo any allotropic transformation at 768° C. The crystal lattice of austenite and of pure iron at 1000° C. is different from that of iron at the ordinary temperature. In martensite the iron atoms are grouped in exactly the same way as in α iron.

Further papers, which were not discussed, included "The Protection of Iron with Paint," by J. N. Friend, "Slip-Lines and Twinning in Electro-deposited Iron," by W. E. Hughes, "The Scientific Control of Combustion," by H. T. Ringrose, and "Comparison of Different Methods of Estimating Sulphur in Steel," by T. E. Rooney.

ROYAL PHOTOGRAPHIC SOCIETY.

At the meeting held on April 26 Mr. Chapman Jones gave a memorial lecture on Sir W. de W. Abney, one of the best-known workers in scientific photography, president of the Society in 1892—1894, 1896, and 1903—1905, and for many years the Honorary Editor of the Society's Journal. Mr. Jones prefaced his lecture with a short account of Abney's work and interests other than photographic. He was artist, archeologist, and astronomer, and, more particularly, an organiser and missionary in the application of scientific method to teaching. He was for many years associated with the Science and Art Department, and had considerable success in urging the necessity for adding practical work to class teaching. His researches in photography and allied subjects covered a very wide field. He was the first to apply spectroscopy to photographic research, and closely associated with this was his work on colour vision, colour measurement, and the principles of three-colour photography. He studied also the continuating action of light on bichromated gelatin, various problems concerned with photographic development, the efficiency and speed of shutters, and sensitometry. His work on emulsions included the production of plates specially sensitive to the infra-red, a problem which he studied both from the standpoint of the addition of materials to "weight the silver bromide molecule" and from that of the formation of a blue emulsion with strong absorption in the far-red. Both in this and in other work he several times anticipated modern research, having noticed, for instance, red-sensitising by treatment of plates with sodium sulphite, and having made use of wedge screens, both of silver and of platinum burned into the glass, in density measurements. Abney's activities were so numerous that the lecturer had time for very little more than to indicate their scope, the work on red-sensitive emulsions being treated in more detail; the printed lecture will include a bibliography.

ROYAL SOCIETY OF ARTS.

In a paper on "Paper Pulp Supplies from India" read before the Indian Section on May 3, Mr. W. Raitt discussed the possibilities of bamboo as the paper-making material of the future, having regard to the fact that the available supplies of timber for wood-pulp manufacture are rapidly becoming exhausted.

The present world consumption of paper may be put at 12 million tons per annum, 80 per cent. of which is made from wood pulp. It is estimated that India can produce annually 10 million tons of bamboo pulp and 3 million tons of pulp from Savannah grasses, and could therefore supply the whole world. Care and experience are necessary to avoid too frequent cropping of the bamboo, whereby its reproductive powers are impaired, but making allowances for these enforced rest periods, a 20,000-acre reserve should keep a factory with an output of 10,000 tons per annum running indefinitely.

Hitherto the chief difficulty in dealing with bamboo has been the high bleach-consumption of the boiled pulp. This may be avoided by modifying the conditions of boiling so that the starchy bodies and pectoses, which are mainly responsible for staining the pulp, are removed before the protective coating of lignin is removed from cellulose. This may be effected by subjecting the bamboo to a preliminary digestion with 1 or 2 per cent. soda at a temperature not exceeding 120° C. This treatment removes both starch products and pectoses without attacking the lignin. Further digestion with 4 per cent. soda at temperatures above 130° C. removes the lignin, leaving a pulp which bleaches comparatively easily. By this method of fractional

digestion, the soda figure is reduced from 26 to 19 per cent., and the consumption of bleach of the boiled pulp drops from 16 to 11 per cent. The sulphate process of boiling can be modified in a similar way, but offers no advantages over the soda process. The treatment of the bamboo before boiling may consist in chipping or crushing. The latter method, though producing a more bulky charge, makes for better penetration and therefore better digestion.

It is estimated that bamboo could be transported to manufacturing sites in Burma at a cost of 12s. 6d. to 15s. per ton, equivalent to £1 11s. 3d. to £1 17s. 6d. per ton of unbleached pulp; the cost of manufacture would be under £10 per ton of pulp, so that taking £4 per ton as the future normal freightage, unbleached bamboo pulp could be delivered in this country for £16—£18 per ton, a figure which should compare very favourably with that of mechanical wood pulp. These figures are based upon estimated future costs of production when the present inflation of prices has passed.

THE FARADAY SOCIETY.

A meeting of the Faraday Society was held on May 9, Prof. A. W. Porter presiding. Mr. U. R. Evans introduced a paper by Dr. E. K. Rideal and himself on the Problem of the Fuel Cell, which dealt with attempts by the authors and others to obtain electrical energy by utilising carbon, directly as coal, charcoal, etc., or indirectly in the form of its combustion or reaction products, as one of the elements of a primary cell.

Fuel cells may be classified under three headings: —(1) Direct fuel cells burning solid fuel, which suffer from current polarisation due to the low velocity with which carbon enters into electrodic reactions. (2) Semi-direct fuel cells using gaseous substances derived from coal, etc., which are used to saturate the negative electrode; these also suffer from current polarisation owing to the difficulty of keeping the electrode material saturated with gas. This was overcome by Mond and Langer, but only by the loss of considerable quantities of platinum from the cell. (3) Indirect cells; these include (a) oxidation-reduction cells, in which the oxidising and reducing agents present in solution in the two compartments are re-generated by fuels and air respectively; the regeneration may take place in the compartment or externally; these suffer from both current polarisation, depending on electrode area, and time polarisation, dependent on the volume of the cell; (b) metal-anode cells, in which a metal obtained by reduction with fuel is used in the solid or the liquid state as the attackable electrode. A metal of low melting-point is desirable.

The authors' experiments on semi-direct fuel-cells, using nickel as the substratum of a gas-electrode, were unsuccessful. More promising results were obtained with the metal-anode type; zinc appeared unsuitable and difficulties were encountered with lead, but better results were obtained with cells (both hot and cold) in which tin formed the active element. The authors' results are, however, admittedly mainly of a negative character.

A paper by Dr. A. Ferguson described a "New Method for determining Surface Tension." Instead of measuring the height to which a column of liquid rises in a capillary tube, external pressure is applied to force the level of the liquid to the bottom of the tube, this pressure being measured by a delicate manometer. Among the advantages claimed for this method are that it avoids difficulties due to variations in tube diameter and to variations in temperature in the capillary tube itself; also the capillary tube may be very short, which facilitates cleaning. The method is rapid in use, and it gives results which are in good agreement with those obtained by the best methods previously known.

A paper by Mr. L. F. Knapp on "The Solubility of Small Particles and the Stability of Colloids" was taken as read.

THE METASTABILITY OF MATTER.

Lectures on "The Metastability of Matter and its Bearings on Chemistry and Physics" were delivered on May 10 and 12 at University College, London, by Prof. Ernst Cohen, of Utrecht University, a distinguished worker in the field of allotropy and polymorphism.

The first lecture was devoted to a general description of metastability as exhibited by elements. Enantiotropy was illustrated by reference to the grey and white forms of tin, and a striking experiment was performed showing that a contraction in volume of 30 per cent. occurs when grey tin is converted into white tin, an electrolyte being added to accelerate the conversion. The explosive form of antimony was taken as an example of monotropic allotropy, *i.e.*, of the existence of one form of an element which is unstable at all temperatures and pressures. Specimens of this form of antimony had been brought from Holland, and those which had survived the journey were shown to emit great heat when they were reconverted into ordinary antimony by scratching, 20 cal. from each gram of metal being evolved. The allotropy of non-metallic elements was discussed by reference to sulphur.

In the second lecture, Prof. Cohen reviewed the phenomena of metastability as exhibited by compounds. Polymorphism among compounds is often shown by differences in colour. Thus thallous picrate occurs in red and yellow varieties, the transition point being 36° C., but the yellow variety is obtained in a metastable form if cooled from above 36° C., and the red variety, if dry, can be heated up to 100° C. without changing into the yellow. Similar phenomena are shown by the black and red forms of mercuric sulphide. In all such cases, the conversion of the metastable form into the stable form at ordinary temperatures takes place slowly, but is accelerated by the presence of a very small amount of an electrolyte. Cadmium iodide was taken as an example of a salt existing in two forms possessing the same colour—the α or stable form of sp. gr. 5·8 and the β or metastable form of sp. gr. 4·8. The difficulty of crystallising cadmium iodide from solutions was shown to be due to the presence of a minute quantity of cadmium hydroxide Ordinary cadmium iodide is a mixture of the α and β varieties. On dissolving the salt in water, the β form is converted to the stable α form, but the crystals separated from the solution consist of a mixture of both. The β form can be converted completely to the α form by heating to 150° C., but it has hitherto not been possible to obtain the β form pure; a mixture containing about 50 per cent. of the β variety is obtained by distilling the mixed compounds and cooling the sublimate in a stream of carbon dioxide. As further examples of metastability, reference was made to quartz, which exists in seven forms, to water, which exists in five modifications, and to calcium carbonate (calcite and arragonite). Lead nitrate exists in two modifications which exhibit a difference of about 2½ per cent. in their respective heats of solution in water. Among other substances which have been definitely ascertained to exist in more than one form are antimony iodide, potassium sulphate, barium sulphate, zinc sulphide, ammonium chloride, silver iodide, caustic soda, sodium tungstate, carbon tetrachloride, phenol, and urea. The existence of such modifications calls for a re-determination of the physical "constants" of very many substances.

NEWS AND NOTES.

FRANCE.

Industrial Notes.—*Chemicals and Fertilisers.*—Prices of heavy chemicals are falling gradually, especially those which a short time ago were greatly inflated owing to deficient supplies. Thus sodium sulphide, which a few months ago fetched 200 francs per 100 kg. is now selling at 65—70 fr. Recently published statistics of consumption of fertilisers show that the present supply exceeds the demand. There are large stocks of superphosphate; during the first few months of this year imports of rock phosphate from North Africa were only 165,000 t., as against 220,000 t. expected, and the price has been lowered to facilitate sales. On account of the small demand, basic slag has been re-inserted on the export free list. Ammonium nitrate is in poor demand, and owing to the arrival of 2400 t. of ammonium sulphate from Germany its price has been reduced to 30 fr. per 100 kg. But very little sodium nitrate is being purchased, the low value of the franc preventing purchases on the London market. The production of crude Alsatian potash in 1920 was 1,061,197 t., of which 450,000 t. was consumed in the country, 327,000 t. exported to America, 117,000 t. to Belgium, and 92,000 t. to England.

Metallurgy.—Little change is perceptible in the metallurgical market, but the acceptance of the Allied terms by Germany has induced a feeling of confidence which is benefiting the country economically and tending to make prices more stable. The high railway rates charged for metallurgical products are causing some anxiety, and there is a movement directed towards obtaining such modifications as will enable costs to be reduced. It is freely rumoured that an agreement will shortly be made between France and Italy by which:—(1) Italy will receive 100,000 metric tons of coal per month from the Saar coalfield. (2) French works will supply Italy with 35,000 t. of pig iron and 50,000 t. of semi-finished and finished products. (3) France will take from Italy 150,000 t. of iron scrap yearly, and more if Italy will purchase more pig iron from France.

Coal.—Owing to the coal strike in Great Britain, stocks of coal have considerably diminished during the past three weeks, particularly in the northern coalfields; they now aggregate some 600,000 t., which is still twice the amount usually held at this time of the year. Fuel consumption, however, will increase, especially when the anticipated revival in the metallurgical and glass industries takes place.

Petroleum.—Negotiations between France and Poland relating to the working of the Polish petroleum fields are reported to be progressing favourably. The agreement, it is stated, provides that in the event of war Poland would refuse to supply France's enemies with liquid fuel. At present French interests hold 60 per cent. of the total capital invested in the Polish oil industry and 80 per cent. of that invested in the refining industry. Many foreign undertakings are attempting to secure an interest in the industry, but Poland will only favour those that are backed by the French Government.

The Nitrogen Industry.—A Bill will shortly be presented to the French Chamber for sanctioning an agreement between the Ministry of War and the Société des Produits Azotés, by which the latter will take over the electrochemical works at Lannemezan and the hydro-electric works at Bordères-Louron and Lendenvielle for a period of 70 years. The company undertakes to increase the capacity of the plant to 20,000 tons of cyanamide and a similar quantity of carbide per annum, and the State will share the profits and receive certain dues.—(*Chem. Ind., Apr.* 25, 1921.)

UNITED STATES.

Nitrogen Fixation Plants.—The Secretary of War has ruled that pending the further development of the nitrogen-fixation industry by private interests, the Government plants at Sheffield, Ala., and at Muscle Shoals are to be retained under Army control in the most economical stand-by condition; and the Fixed Nitrogen Research Laboratory at American University, Washington, D.C., is also to be retained and continued under the War Department.

The Government Kelp Plant.—The United States Government kelp-plant is to be sold as soon as possible after July 1. The plant has been operated to determine whether carbon black, iodine, and potash salts can be recovered on a commercial basis, and it has treated 100 tons of wet kelp per day from which, it is claimed, 1500 lb. of carbon and two tons of potash salts are obtainable. The Bureau of Soils is more interested in finding a customer who will continue the experiments than one willing to pay a high price. The plant is being sold in accordance with the recent Agricultural Appropriation Bill.

Spring Meeting of the American Chemical Society.—The meeting held at Rochester under the presidency of Prof. Edgar F. Smith during the last week in April was one of the largest of its kind; more than 1300 attended and 282 papers were presented in eleven divisions and sections. The congestion of papers has led some of the divisions and sections to appoint committees to examine and revise papers beforehand and to decide whether they shall be read in abstract or *in extenso*, or not at all.

Dr. E. K. Mees gave an address on "The Measurement of Colour," Prof. Wilder D. Bancroft on "Blue Eyes and Blue Feathers," Dr. R. E. Wilson one on "Surface Films as Plastic Solids," and Prof. Irving Muir discoursed on "The Relation between the Stability and the Structure of Molecules." The new Petroleum Section made an auspicious beginning under the chairmanship of Dr. T. G. Delbridge, of Philadelphia; among a large number of papers presented to it was one by Dr. C. F. Mabery on the separation of non-volatile hydrocarbons by fractional solubility in hot ether-alcohol mixtures.

The Division of Industrial and Engineering Chemistry held a symposium of "Drying," a paper by W. K. Lewis on "The Rate of Drying Solid Materials" being one of the more interesting. A symposium which attracted much attention was that on "Our Future Supplies of Liquid Fuel." Prof. H. N. Whitford, of the Yale University School of Forestry, urged the conversion into alcohol of vast quantities of such tropical vegetation as cassava, nipa palm, or bamboo, and two other speakers advocated utilising the enormous quantities of waste wood in the U.S. forests. Better methods of agriculture and of conserving food products were proposed in the Division of Agricultural and Food Chemistry. One speaker described new groundnut by-products; four chemists suggested improved methods for the making of ice cream; another gave hints on preventing the discoloration of canned sweet potatoes; and a most helpful paper related to improvements in the manufacture of cheese. There was also an elaborate report on means of preventing the mosaic disease of spinach.

Advanced methods of manufacture considered by the Section of Sugar Chemistry and Technology should have an important influence on the production of sugar and may tend to stabilise prices. There seemed, however, to be no indication of a drop in the cost of the so-called "rare sugars," such as mannose, which is made from the shavings of the Ecuador ivory nut discarded from the button factories, and is now $142 per lb. These sugars are used for the detection of disease germs.

In the Dye Division a new process for producing alizarin from benzene as initial material was outlined by C. W. Schaffer, and a new method of making Malachite Green was also reported. A method for detecting and estimating carbon monoxide, based on the colour-change of a mixture of fuming sulphuric acid and iodine pentoxide, was described by C. R. Hoover; and the Division of the Chemistry of Medicinal Products discussed new non-habit-forming drugs to take the place of those narcotics which enslave. An interesting feature of the meeting was the visit to Kodak Park, the largest of the works of the Eastman Kodak Co. at Rochester, which produces about 125,000 miles of kinematograph films, uses over 1300 tons of cotton and over 150 tons of pure silver yearly.

The membership number of the Society at the end of 1920 was 15,582.

Phosphate Rock in 1919.—The phosphate rock marketed in the United States in 1919 amounted to 2,271,983 long tons, valued at $11,591,268, which showed a decrease in quantity of 9 per cent. and an increase in value of 41 per cent. over the figures for 1918. The actual quantity mined was 1,851,549 tons, or nearly 19 per cent. less than in 1918. There was an increase in the output from South Carolina, Tennessee and the Western States, but production in Florida, the chief producing State, fell by 20 per cent. owing to a prolonged strike. Exports fell during the war to only about one-tenth of their pre-war volume, having declined from 1,300,000 long tons in 1913 to about 143,000 t. in 1918, but in 1919 they improved to over 378,731 t. In 1920 the total quantity marketed was 4,103,982 long tons (Florida 82%, Tennessee 16%), and the exports rose to 1,070,012 t. The market for American phosphate in Southern European States is bound to be small because France and Spain have ample supplies available from Tunis and Algeria, and have greatly increased their capacity to manufacture sulphuric acid.

(For the world's production in 1913, 1915, and 1916, *cf.* J., 1920, 168 R.)—*U.S. Geol. Surv., Feb., Mar.,* 1921.)

Strontium in 1919.—Strontium ore was first mined in the United States in 1916, when, under the stimulus of high prices and war needs, 250 short tons was produced and marketed. In 1917, 4305 t. was marketed, in 1918, 400 t., and in 1919 there was no production at all. During 1919, 1393 t. of crude celestine was imported from England, and also certain manufactured salts. The production of salts, chiefly the nitrate, was 1,387,555 lb.; the carbonate was also made, mostly for use in the manufacture of other salts, but some was used for experimental work in sugar-refining. Should these experiments lead to the general adoption of strontium compounds for the refining of beet sugar in the United States and Canada, the mining of strontium ore would be revived on a large scale. As is well known, strontium salts are used chiefly in the manufacture of fireworks, signal lights, and medicines. A little strontium is alloyed with copper in making castings, to harden the copper and to prevent the formation of blow-holes. For this purpose the alloy is obtained either by adding to the melt a little metallic strontium, or by electrolysing fused strontium chloride, using a copper cathode. The small amount of strontium introduced into the copper does not affect its electric conductivity.—(*U.S. Geol. Surv., Dec.* 5, 1920.)

AUSTRALIA.

A Proposed New Industry for Victoria.—At Bendigo, in Victoria, works are proposed for the manufacture of paints and glazing preparations for pottery-ware. Pottery is already produced in the neighbourhood. Large deposits of red ochre and hæmatite in the district are to be developed, and these will provide the raw material. A site for the works has been secured close to the Bendigo-Echuca railway line.—(*Hardware and Machinery, Feb.* 4, 1921.)

The Sugar Situation.—It is announced that the Commonwealth Government will continue to pay Australian sugar growers £30 6s. 8d. a ton for raw sugar during the current year, wholesale and retail prices being fixed at £49 per ton (refined) and 6d. per lb., respectively. The crop for 1920–21 is expected to be heavy and will, it is hoped, suffice for requirements, in which case the price may be reduced. Up to June 30, 1920, the Commonwealth Government had lost over £900,000 on its sugar transactions, but these losses will probably be recovered by August 1, 1921. Imports of sugar during the last two years were:—1918–19, 52,569 t. (£1,052,124); 1919–20, 112,805 t. (£4,359,203); Dec. 31, 1920, 24,475 t. (£1,059,342).—(*Bd. of Trade J., May* 19, 1921.)

BRITISH INDIA.

Indian Bauxite.—In the first number of the *Journal of Industries and Labour* Dr. J. Coggin Brown, of the Geological Survey of India, contributes an article on bauxite with special reference to its occurrence and exploitation in India. The richest areas yet discovered are on the Baihir plateau, in the Balaghat district, and near Katni, in the Jubbulpore district, both in the Central Provinces. Valuable ores are also found in the Mandla and Seoni districts of the Central Provinces and in the States of Sarguja and Jashpur. The Balaghat bauxite, like that of Jubbulpore, is of very high grade, and there seems little doubt that large quantities are available; eight analyses of samples gave: Al_2O_3, 51·62—58·83%; Fe_2O_3, 2·70—10·58%; TiO_2, 6·22—13·76%; and combined water, 22·76—30·72%. Occurrences of limited extent but of excellent quality exist in Western Chota Nagpur, and considerable amounts of the mineral are associated with the iron ores of the Bababudan Hills. A series of analyses of samples from the Kemmangundi area gave: Al_2O_3, 34·20—62·50%; Fe_2O_3, 5·10—40·70%; SiO_2, 0·26—13·60%; and water, 20·00—31·90%. Further deposits have been found in the Bhopal, Rewah, and Tonk States of Central India, the Satara district of Bombay, the Madras Presidency, and elsewhere. The official figures of the output of Indian bauxite, *e.g.*, 1192 tons in 1918, in no way reflect the potentialities of the deposits, which are now being investigated by the Geological Survey with a view to publishing a memoir on the subject.

In 1907 Sir Thomas Holland stated that probably the best means of effecting the large-scale develop-

ment of Indian bauxite was to manufacture pure alumina locally by extraction with alkali for export to aluminium works or for the local manufacture of aluminium salts. Exportation of the raw or calcined material was not practicable, and the installation of aluminium works in India would involve heavy capital outlay under untried conditions and elaborate investigation before power works could be erected. Since then, however, several concessions have been taken out and more extensive knowledge of suitable sites for power stations has been acquired; but in the event of the erection of an aluminium works in India, a part of the production would have to be exported, as the Indian consumption is comparatively small. The success of aluminium enterprises in other countries has depended more on cheap electrical energy and large-scale production than on other factors.

The article also contains useful information on grades and specifications, markets, prices, and chief sources of supply.

JAPAN.

Petroleum Production.—The Department of Agriculture and Commerce, Tokyo, has issued the following statistics of production of crude petroleum and its distillation products during the period 1917–20. In the appended table the quantities are given in barrels of 35 Imperial gallons, and natural gas is included under "crude oil":—

	1917.	1918.	1919.	1920.
		Thousands of barrels.		
Total crude oil	2949·4	2535·4	2350·5	2364·1
Naphtha	141·8	166·8	167·9	165·6
Lighting oil	517·3	349·4	276·8	209·9
Light oil	697·7	744·2	657·9	697·7
Lubricating oil	400·4	393·6	415·2	442·4
Heavy oil	622·8	376·6	224·6	209·9

—(*Ch. of Comm. J., May* 6, 1921.)

GENERAL.

Lead Poisoning.—Referring to Dr. Miall's remarks on lead poisoning in a recent issue of this Journal (p. 140 R), Miss Helen Masters, of King's College for Women, University of London, writes that safeguarding the health of the workers is not the only aspect of the problem, and that the possibility of the public suffering from the use of lead glazes on cooking utensils must also be taken into consideration. Miss Masters published in the *Analyst* (1919) and in the *Lancet* (1920) the results of her examination of glazed earthenware casseroles of English, French, and Dutch manufacture, which showed that practically all of them yielded soluble lead compounds on boiling with dilute solutions of organic acids such as might be present in ordinary cooking processes, and she adduced other evidence of the danger of using such lead-glazed ware. In the interests of public health she now advocates either that the use of lead glaze for cooking utensils should be prohibited, or that a standard test be adopted to which such vessels should be submitted before being placed on the market.

Tetrachlorethane Poisoning.—Tetrachlorethane, the non-inflammable solvent which came into prominence during the war as a constituent of aeroplane "dopes," is now used industrially as a solvent for cellulose esters, etc., in the manufacture of such articles as non-inflammable films, lacquered goods, and artificial silk. In a paper in the April issue of the *Journal of Industrial Hygiene* Dr. D. C. Parmenter, of Harvard University, describes the symptoms of tetrachlorethane poisoning and discusses methods of prevention. His observations were made in an artificial-silk factory and extended over five months, during which period twenty-one cases of poisoning occurred, but no fatalities. The initial symptoms are abnormal fatigue, discontent, general nervousness, and loss of appetite, and as the poisoning progresses these are accompanied by nausea and vomiting. Such symptoms, although often not marked, are nevertheless detectable by careful observation, and their proper interpretation, together with a clear understanding of the importance of the blood findings, makes possible the prevention of all but the very slight cases of poisoning. Ventilation is an important preventive, and the wearing of gas-masks is recommended in special cases, *e.g.*, in dissolving cellulose acetate and in working with acetic anhydride. Dr. Parmenter concludes that the industrial use of tetrachlorethane presents no more difficulties than that of benzol, TNT, or lead.

Chemical Industry in Germany.—In consequence of the "Sanctions," the demand for chemical wares has greatly diminished, and export business has practically been at a standstill since the beginning of April. It is anticipated that the exports for the first half of this year will show a very considerable falling off from those of the corresponding period of 1920, when 1,482,421 metric tons of chemicals, drugs, dyes, etc., valued at 4560 million mk., was exported (the corresponding figure for 1914 was 2,415,550 t.). The exports for Jan.-June, 1920, included:—Potash salts, 527,960 t. (807 million mk.); coal-tar dyes, 8850 t (849 mill. mk.); indigo and indigo-carmine, 4506 (257 mill. mk.); alizarin and alizarin dyes, 2004 t. (134 mill. mk.). Although the nitrogen factories have been fully employed, production has seriously declined in practically all other branches of the chemical industry.

Exportation of chemicals continues under the control of the "Aussenhandelstelle Chemie" (Export Bureau) in Berlin, which was established in June, 1919, as an autonomous organisation for the chemical industry to be conducted on strictly business lines. It is subdivided into sections corresponding to the chief divisions of chemical industry; it issues licences for importing and exporting chemical products, and fixes minimum prices for exported goods. The fees charged by the Bureau for its services are 1 mark per 1000 marks of the value for export, and 30 pfg. per 1000 marks of the import value.

A small book entitled "Chemicalia" has just been published in Berlin that is designed to take the place of the well-known reference-book "Wenzel," which has not been on sale for about ten years. The new book gives the names, addresses, etc., of all the important chemical manufacturing firms, together with a list of their specialities in the German, English, French, and Spanish languages, and it contains much other information of value to producers, consumers, and traders.

The Chemical Industries of Upper Silesia.—Both before and during the war the chemical industries of Poland were very undeveloped, and the country's requirements in fertilisers, dyes, drugs, and substitutes for textile finishing, etc. were derived in a large measure from Upper Silesia, where chemical industries were first established in the period 1867—1880. At that time there were only about ten manufacturing firms of any consequence, and at the present time only one of these employs more than 100 full-time workers. Between 1890 and 1900 development proceeded apace, and the two largest undertakings established during this period—the Rütgers-Werke and the A.-G. Lignose Konzerns—still play an important part in the chemical industry of Upper Silesia; the former produces manufactured fuel, electrodes, etc., employs 1300 workers, and has a capital of 40—50 million marks, and the latter manufactures ammonium nitrate, nitric acid, explosives, etc., and employs over 1000 workers. The period 1900—1910 saw the establishment, in Gleiwitz, of a branch of the Griesheim Elektron company, which produces mainly oxygen, the Oberschlesische Farbwerk, Idaweiche (litho-

pone), the Oberschlesische Thomas-Phosphatwerke, Sczepanowitz near Oppeln (fertilisers), the Mineralölraffinerie Idaweiche (mineral-oil lubricants, etc.), the Oberschlesische Isoliermittel, G. C. Flegel and Co., Kattowitz, the Chemische Werke Carbon at Ratibor, and others. During the war period and after, the following new undertakings have been established:—The A.-G. Lignose, Kriewald, and the Chemische Fabrik von Heyden, Kostucha, both of which make potassium chlorate; the Oberschlesische Zellstoffwerke, Krappitz (cellulose, etc.), with a capital of 1·5 million mk.; the Oberschlesische Phosphatwerke, Oppeln, founded in 1919 with a capital of 300,000 mk. A small water-glass factory was erected in Hindenburg in 1918, and in 1920 the Oberschlesische Stickstoffwerke was established to acquire, erect, and manage nitrogen factories with a (present) capital of 250,000 mk. The Oberschlesische Zinkhütten (zinc smelters) in Kattowitz, which dates from a much earlier period, produces sulphuric acid from the roasting of blende. It will thus be seen that the chemical industry of Upper Silesia is of considerable magnitude; it comprises 60—80 undertakings, employs about 5000 workers, and commands a total capital of 150—200 million mk., exclusive of the important coke-oven plants. The coking industry has steadily developed in recent years, and early in 1920 the individual firms formed a company—the Chemische Werke Oberschlesiens—for the purpose of jointly working up and selling their entire production of tar and ammonia. The Oberschlesische Kokswerke und Chemische Fabriken, which was founded in 1890 and is now working with a capital of 35 million mk., has plants at Stalley (195 ovens), Zabrze (75 ovens), Poremba (220 ovens), and Glückauf (60 ovens); the tar is worked up by the Oberschlesische Gesellschaft für Teerverwertung, the tar oils are sold by the Verkaufsvereinigung für Teererzeugung in Essen, the pitch is taken by the Upper Silesian briquette factories, and the ammonia is converted into sulphate and distributed through the Nitrogen Syndicate in Berlin.—(*Chem.-Z.*, *Apr.* 26, 1921.)

Austrian Magnesite.—Owing to the extraordinary demand for this mineral, many developments are taking place; new and valuable deposits have been discovered and exploited, and production is to be carried on at maximum capacity. The mines are all situated in present-day Austria, and all the more important belong to the Veitscher Magnesitwerke A.-G., which operates the Veitsch and Trieben mines in Styria and the Breitenau mine in Lower Austria. The life of the Veitsch mines is estimated to be 200 years at the present rate of production. Last year a French-Swiss group, which included the Schneider-Creusot Co., acquired an interest in this undertaking; profits were 23 million kronen and a dividend of 40 per cent. was paid (4 mill. kr. and 10 per cent. in 1919). Among recent developments may be noted the formation of the Steirische Magnesitindustrie A.-G., with plants at Oberdorf and Neuberg, the discovery of promising deposits at Mayrhofen, acquired by the Veitsch company, and the working of valuable deposits near Kraubath; the Salzburger Magnesit Industrie Gesellschaft is planning the exploitation of mines in the Salzburg country, and a new company is operating the mines at St. Martin in Styria. During 1913, 123,900 t. of the calcined mineral was exported, and in 1920 about 63,000 t.—(*Times Tr. Supp.*, *May* 14, 1921.)

German Beet-Sugar Production in 1920–21.—The German beet-sugar crop for 1920–21 is estimated to be about 1,200,000 tons, an amount which will enable household rations to be increased and permit of distribution to all industries. It is announced that the internal tax on sugar is to be increased to 100 mk. per 100 kg., and with the mark at its present value the result would be to favour export of sugar, as in comparison with the world value the tax is nominal on the prices made by exported sugar. Germany's consumption, however, is much higher than the production, and export is unlikely. —(*Ind. Tr. J.*, *Apr.* 1, 1921.)

Production of Blackstrap Molasses in Cuba.—The estimated production of blackstrap molasses in Cuba in 1920 was 180 million gallons (U.S.A.), of which 20—30 million galls. was used locally in the production of fuel alcohol. The storage and conservation of the molasses by the sugar mills largely depends on the market price, and much of it is burned at the sugar factories as fuel. The demand is expected to increase, especially if alcohol comes into use as a motor fuel. Shipments of blackstrap molasses from Cuba amounted to 199,193,722 galls. in 1917, 163,716,219 galls. in 1918, and 49,782,231 galls. in the first six months of 1919.—(*U.S. Com. Rep.*, *Mar.* 5, 1921.)

Sugar-Beet Cultivation in Shantung.—The announcement that a beet-sugar factory is to be established at Wangtaichiao, near Tsinanfu, by a Chinese company, the Pu Yih Industrial Co., marks the first attempt to establish a beet-sugar industry in Shantung. Machinery is being obtained from the United States and Japan, and sugar-beet seed is being distributed in the districts around Tsinanfu. Favourable conditions of soil, climate, and water supply appear to obtain in Shantung, and with abundant cheap labour, the success of the enterprise would seem to be assured. The company has secured a monopoly of the industry for 24 of the 100 or more districts in Shantung.—(*U.S. Com. Rep.*, *Mar.* 5, 1921.)

The World's Petroleum Output in 1920.—The American Petroleum Institute estimates the world's production of petroleum in 1920 at 688,474,251 barrels, which represents an increase of 24·2 per cent. over the previous year. The estimated production in barrels by countries is as follows:—

	1919 Barrels.	1920 Barrels.
United States	377,719,000	443,402,000
Mexico	87,072,954	159,800,000
Russia	34,284,000	30,000,000
Dutch East India	15,780,000	16,000,000
India	8,453,000	8,500,000
Rumania	6,517,748	7,406,318
Persia	6,289,812	6,604,734
Galicia	6,255,000	6,000,000
Peru	2,561,000	2,790,000
Japan and Formosa	2,120,500	2,213,083
Trinidad	2,780,000	1,628,637
Argentina	1,504,300	1,366,926
Egypt	1,662,184	1,089,213
France (Alsace-Lorraine)	—	700,000
Venezuela	321,396	500,000
Canada	220,100	220,000
Germany	925,000	215,340
Italy	38,254	38,000
Total	554,505,048	688,474,251

In 1920 the United States produced 64·4 per cent. and Mexico 23·2 per cent. of the world's output.—(*Min. Mag.*, *Apr.*, 1921.)

Wood-pulp Manufacture in Alaska.—The United States Department of Agriculture has recently received samples of the first run of a new pulp-mill established at Juneau, in the Tongass National Forest. The mill, the first to be established in the territory, is operated by hydro-electric power, and has a capacity of 20 tons a day, with power resources available for increasing the output to 250 tons. So far spruce has been utilised, but hemlock will be ground for newsprint purposes, and the eventual manufacture of paper at the mill is planned. An area of the Tongass National Forest containing 2000 million feet of pulp-wood will, it is stated, shortly be placed on the market in response to inquiries from prospective paper manufacturers.—(*Bd. of Trade J.*, *Apr.* 14, 1921.)

Saccharin Monopoly in Yugoslavia.—The Government monopoly of saccharin and other sugar substitutes in Yugoslavia has hitherto been effective in Bosnia and Herzegovina only, but it is now to be applied to the whole State.—(*U.S. Com. Rep., Apr.* 1, 1921.)

Peppermint Distillation in Piedmont.—The cultivation and distillation of peppermint in Piedmont is a small but very profitable industry, as the demand greatly exceeds the production. In 1920 the crop from 1483 acres was 22 million lb., which on distillation yielded 59,525 lb. of peppermint oil, valued at 6 million lire (£240,000 at par). It is anticipated that the crop for 1921 will be roughly 20 per cent. larger than that for 1920, as the distillers have promised higher prices to cultivators in order to increase production.—(*U.S. Com. Rep., Apr.* 13, 1921.)

Fuel Oil from Sicilian Asphalt.—One of the richest areas of the asphalt deposits in Sicily is owned by an Italian company which, in addition to working up the material into products for paving and roofing, has developed a process for the production of mineral oil with a very low bituminous content and a calorific value of 10,300 calories per kg. A large battery of gas furnaces is employed, and the heat of the ash is almost completely recovered by means of a current of the inert gases from the condenser discharges; particles of oil carried over in the combustion fumes are recovered by means of centrifugal filters and condensers. The output for 1920 is estimated to be 5000 metric tons of oil, and is hoped to increase this to 10,000 t. in 1921. The company is planning the erection of a large refinery near Rome.—(*U.S. Com. Rep., Feb.* 11, 1921.)

Sumac Production in Sicily.—Sicily is the largest producer of sumac in the world, the United States taking second place. The annual output in recent years is estimated at 15,000 metric tons, which is 50 per cent. below the pre-war production. This decrease is due to diminished cultivation, which is believed to be only temporary. Male sumac is found in the provinces of Palermo and Girgenti, and contains 28 per cent. or more of tannin, whereas female sumac, found mainly in the provinces of Catania and Girgenti, contains an average of 24 per cent. There are about eight large sumac-grinding mills in Palermo, but no factories for preparing the extract, although it is considered probable that they will be built when the trade revives. Exportation from Palermo is chiefly directed to Great Britain, the United States, France, and Germany (*cf.* J., 1920, 263 R).—(*U.S. Com. Rep., Mar.* 23, 1921.)

Columbian "Pita" Fibre.—The term "pita" is used very widely in Central and South America, and is applied to several fibre plants (including sisal hemp) and also to string. Colombian "pita" belongs to the *Bromeliaceæ* and is a species of *Ananas*, closely allied to the pineapple; it grows in the shade of forest trees, forming extensive, impenetrable areas known as "pitales," but it can be grown on light open land and at altitudes ranging from sea-level to 3000 ft. The fibre is said to be superior to sisal in strength, fineness, and durability, and if available commercially it would compete with sisal hemp in the manufacture of rope and twine. The average annual yield of the forest "pitales" is estimated to be 45·5 tons of leaves containing 5 per cent. of fibre. By the native method of extraction about 40 per cent. of the fibre is wasted, so that if 3 per cent. could be obtained by mechanical extraction, the yield would be about 1·5 tons of dry fibre per acre. Certain advantages are claimed from the harvesting of fibre from the natural "pitales" as compared with cultivation of sisal plantations, but the difficulty is that no machine is yet available for extracting the fibre from the leaves.—(*Imp. Inst. Bull.*, XVIII., No. 4.)

The Industrial Value of Perilla Seed.—In view of the increased demand for drying oils, it has been thought that the cultivation of Perilla seed (*Perilla ocymoides*) might be encouraged in British possessions; at present it is grown for commercial purposes principally in Manchuria, China, and Japan. To this end the Imperial Institute sent out samples of Japanese seed to India, East Africa, South Africa, Rhodesia, and Cyprus for trial cultivation, and a report from Cyprus is now published in the *Bulletin of the Imperial Institute*, Vol. XVIII, No. 4. The seeds contained 6·3 per cent. of moisture and yielded 43·1 per cent. of oil (46 per cent. on a dry basis) which possessed the properties of Perilla-seed oil, and which should be readily saleable in this country for paint and varnish making and other purposes for which a drying oil is required. The residual meal contained 35·6 per cent. of protein and 18·9 per cent. of fibre, and would probably be a valuable feeding stuff; trials, however, are required to determine this point. The authorities in Cyprus have been asked to continue the experiments.

Finsbury Technical College.—The threatened closure of this valuable institution having been averted (*cf.* J., 1921, 150 R), the Governing Body announces that the entrance examination for the session 1921—22 will be held on September 20 next. Applications for admission should be forwarded to the College not later than September 15 on forms to be obtained from the Registrar, Leonard Street, City Road, E.C. The programme of the College is under revision and will be issued in due course.

PERSONALIA.

Mr. W. B. Worthington has been elected president of the Institution of Civil Engineers for the year 1921-22.

The list of newly elected foreign members of the Royal Society includes the names of Prof. Albin Haller and Prof. P. Zeeman.

Mr. C. R. Delong has succeeded Dr. Grinnell Jones as chief of the Chemical Division of the United States Tariff Commission.

Senator Piero Ginori Conti is succeeding Prof. G. Ciamician as president of the Associazione Italiana di Chimica Generale ed Applicata.

The Willard Gibbs Medal of the Chicago Section of the American Chemical Society is to be presented to Madame Curie at a special meeting to be held on June 14.

The University of Glasgow is to confer the honorary degree of LL.D. upon Sir Dugald Clerk and Prof. J. C. Irvine, principal of St. Andrew's University.

Prof. P. H. M.-P. Brinton, head of the chemical department in the University of Arizona, has been appointed professor of analytical chemistry in the University of Minnesota.

The Court of the University of Manchester has conferred the honorary degree of Doctor of Science upon Sir E. Rutherford, formerly professor of physics in the University.

Sir J. J. Thomson has been elected honorary professor of natural philosophy, and Sir Ernest Rutherford professor of natural philosophy, in the Royal Institution of Great Britain.

The death of Dr. E. B. Rosa, chief physicist to the Bureau of Standards, Washington, D.C., is announced by *The Times*.

PARLIAMENTARY NEWS.

HOUSE OF COMMONS.

Wage-Reduction in Industries.

In a long written reply to Sir W. de Frece Dr. Macnamara gave a list of the industries in which wages have been reduced in recent months. The list includes chemicals; soap and candles; bleaching, dyeing and finishing; iron-ore, shale, fireclay, and gypsum mining; limestone quarrying; iron and steel; coke and by-products; tinplate; glass-bottle manufacture.—(May 6.)

Arseno-Benzol Treatment of Venereal Disease.

Replying to Mr. R. Richardson, the Minister of Health (Sir A. Mond) stated that 22 deaths had been reported from the administration of arseno-benzol at centres for the treatment of venereal disease; in three of these cases death was not due to the drug, and in five others it was not certain how far the drug had contributed to the fatal result. In the last complete year for which statistics were available the administration of the drug might have been a contributory cause of, roughly, one death in every 4300 patients treated for syphilis, and of one death in every 30,000 injections. The suggestion that such information as the above should be included in a Departmental report would be considered.—(May 12.)

Home-Grown Sugar, Ltd.

Mr. Young, in answer to Lieut.-Col. Nall, said that it was proposed to make an advance, under certain conditions, to Home Grown Sugar, Ltd., on second mortgage of the sum of £125,000 recently voted for the purpose on the estimate of the Ministry of Agriculture. In addition, Parliament would be asked, if necessary, to provide in each of the ten years ending March 31, 1930, a sum that with the divisible profits of the company would enable 5 per cent. per annum to be paid on the £250,000 ordinary shares issued to the public, such advances to be repayable out of future profits. It was hoped that the arrangements would not prove to involve any subsidy, but in any case the agreements made between the Government and the company could not be reconsidered (*cf.* J., 1920, 223 R, 1921, 108 R).—(May 13.)

German Reparation (Recovery) Act.

Mr. Chamberlain, answering Capt. Wedgwood Benn, said that the Government would not repeal or suspend the above Act until it had had further experience of the working of the terms to which Germany had just subscribed, but the rate of duty would be reduced to 26 per cent., and its collection here would be in lieu of and not in addition to the general levy on all exports collected in Germany.—(May 13.)

Safeguarding of Industries.

The two financial Resolutions dealing with "key" industries, dumping, and depreciated exchange (*cf.* J., 1921, 131 R) were considered on May 9, 10, and 11, and passed without amendment. In introducing the first Resolution (relating to the 33⅓ per cent. *ad val.* duty on certain imported articles) the President of the Board of Trade based his argument largely on the needs of national defence, and stated (*inter alia*) that the prospects of the chemical industry were illimitable and its development absolutely necessary. Mr. Jameson (West Edinburgh) spoke of the grave danger to which the rubber-tyre industry was exposed owing to competition not only from the United States, but from France and Italy, and of the present widespread unemployment in that industry. Sir J. Norton-Griffiths urged the claims of the gas-mantle industry to be safeguarded, stating that at the present time the works at Wandsworth were virtually shut down. Mr. Hannon asked for protection for the manufacture of electrodes and vitrefied grinding wheels. Dr. Murray opposed the inclusion of optical glass on the ground that microscopes, etc. would become dearer to students of science. Mr. Kiley, in moving to omit beakers, flasks, etc., said that "lamp-blown ware" included common lamp-shades, and a beaker was practically "a glass jug without a handle"; he could not see how the latter could help to win a war. Mr. Lyle-Samuel, in alleging the inferiority of British chemical glassware, said that it appeared to "undergo some form of chemical dissociation" in use, and that it had a "shorter life when exposed to atmospheric conditions." All the proposed amendments were defeated by large majorities.

OFFICIAL TRADE INTELLIGENCE.

(*From the Board of Trade Journal for May* 12 & 19.)

OPENINGS FOR BRITISH TRADE.

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent.	Materials.	Reference number.
British Honduras..	Matches, drugs, medicines, soap, rope	604
British West Indies	Matches, paint, paper, galvanised iron	624
Canada	Pottery, aluminium ware ..	600
New Zealand ..	Glassware	602
South Africa ..	Mining and farmers' supplies ..	623
Bulgaria	Sheet iron, galvanised iron, tin-plate, blackplates	605
Denmark	Laboratory supplies	629
France	Writing and printing paper ..	608
"	Pharmaceutical products, crude drugs, dyes	609
Belgium	Bar iron, crucible steels	610
Serb-Croat-Slovene State	Drugs	615A
Switzerland ..	Oilcake	632
United States ..	Chemicals, dyes	618
Argentina ..	Heavy and fine chemicals ..	619

Markets Sought.—A Canadian manufacturer of bleached sulphite wood pulp invites inquiries from U.K. paper makers. [Inquiries to the Canadian Government Trade Commissioner, 73, Basinghall Street, London, E.C. 2.]

A merchant in British Honduras wishes to get into touch with U.K. importers of logwood, fustic, chicle, and rubber. [604.]

TARIFF. CUSTOMS. EXCISE.

Brazil.—The sanitary stamp tax on pharmaceutical specialities has been revised.

British Guiana.—The forms of certificates of origin for goods imported under the British Preferential tariff are given in the issue for May 12.

Canada.—Hard soap (not being whale-oil or castile soap) is rated for duty under Tariff item No. 228 when the fair market value thereof at the place of manufacture abroad is over 9 cents per lb. wholesale.

Denmark.—All goods arriving at the free port of Copenhagen are now free of export duty.

Egypt.—Benzine and mineral lubricating oil pay customs duty at the rate of 15 per cent. *ad valorem.*

Federated Malay States.—An export duty of 2½ per cent. *ad valorem* has been levied, as from January 1, on china clay, potash and soda felspar, and china stone.

France.—The export of glucose and of certain kinds of rags is now permitted.

Germany.—Among the articles that may be imported without licence, as from April 29, are cork, tanning barks, certain raw hides and skins, raw bones, iron ore, manganese ore, ozokerite, and montan wax.

As from April 29 export licences are no longer required for cork, certain tanning barks, rubber, gutta percha, balata, ozokerite, montan wax, sulphite lyes, soft soap, turkey-red oil, "Creolin," glycerin, paraffin ointment, cart grease, copper sulphate, cryolite, artificial resins, tanning extracts, glue, asbestos manufactures, wire rope, aluminium powder and foil, lead bars, sheet zinc, etc.

Gold Coast.—The import duties on spirits have been revised with effect from April 27.

Japan.—The proposed changes in the import tariff affect, *inter alia*, olein, stearin, paraffin wax, caustic potash and soda, sodium peroxide, potassium, cocaine, cocaine hydrochloride, spiegeleisen, ferromanganese, certain kinds of iron, steel and zinc.

Kenya.—The import of spirits is prohibited unless they have been matured by storage in wood for at least 3 years.

Netherlands.—It is proposed to increase the import duties on beer, candles, chocolate, cork, gunpowder, oil (not specially mentioned), platinum, refined salt, soap, sugar, dextrose, caramel, wood spirit, and alcohol.

Nigeria.—Among the articles of which the import by post is prohibited are German dyestuffs and spirituous liquors.

Poland.—The customs duties have been suspended until July 15 on condensed milk, fertilisers, train oil, margarine, graphite, antimony, sodium sulphate, sulphuric, nitric and hydrochloric acids, dye earths, tanning extracts, pig iron, copper ingots, lead ingots, wood pulp, printing paper, and manilla cord.

Reduced rates of import duty are payable on olein, leather for the textile industry, asbestos sheet and yarn, certain wares of glass and porcelain, hydrosulphite and sulphide of soda, nitrates of thorium, cerium, beryllium, aluminium and magnesium, naphthols and sulphonic derivatives, and sulphuric ether.

Spain.—The export of 20,000 metric tons of olive oil is allowed under licence subject to export duty.

The customs duties on cement have been reimposed as from May 3.

Switzerland.—The import of certain wares of iron, copper and copper alloys is prohibited except under licence as from May 3.

All goods may now be exported under general licence with exceptions which include condensed milk, iron filings or turnings, scrap iron, indigo and coal-tar colours not specially mentioned in the general tariff.

Trinidad and Tobago.—The complete schedules of customs duties are set out in the issue for May 12.

Goods that are free of import duty under the British preferential tariff include blasting gunpowder, butter substitutes, some cattle foods, raw cocoa, coconuts,, certain kinds of glassware, raw rubber, balata, chicle, raw hides and skins, lard, lard substitutes, lime, manure, condensed milk with not less than 7 per cent. of fat, copra, edible oils, scientific apparatus, certain tanning and dyeing materials, tonca beans, serums, and radium.

COMPANY NEWS.

BRITISH COTTON AND WOOL DYERS' ASSOCIATION, LTD.

The twenty-first annual meeting of the Association was held in Manchester on May 13. Mr. A. Hoegger, who presided, said that few would care to experience a repetition of the abnormal conditions which had prevailed during the last six months, or again share in losses similar to those sustained by the textile industries in consequence of the great and sudden fall in prices. Since November last few of the branches of the Association had been able to find work for their employees for more than two or three days a week, but relations with labour continued very cordial; the standard rate of wages for the 48-hour week rose to 80s. 2d. in February last, but had recently been reduced to 70s. 6d.; pieceworkers could earn far higher wages. A comparison of costs for the years ended March, 1914 and 1921, showed that the cost of dyewares had increased by 270 per cent., that of coal by 217 per cent., and that of wages by 196 per cent. Recently there had been a revival of inquiries for all classes of work dealt with by the Association, and, given more settled labour conditions, the textile trades should once again enter upon a period of prosperity.

Referring to the dyestuff situation, Mr. Hoegger quoted the official report which stated that the value of imported coal-tar colours from Jan.—June, 1920, exceeded £5,000,000. Germany, he said, was now making dyes at the rate of about 5000 tons per month, and it had been estimated that the world's output capacity was at least double that of the normal consumption. Excellent work was being done by British makers, but we were not yet entirely independent of Germany; during the past year many good and useful colours not previously made in this country were marketed, but the prices of the vat and other fast dyes were still too high to allow of an extensive business being done. Great progress was necessary to enable our textile trades to meet the ever-increasing competition in dyed and coloured woven goods and prints containing the brilliant and fast dyes so much admired and in such great demand all over the world.

MAYPOLE DAIRY CO., LTD.

Sir W. George Watson, addressing the annual meeting held in London on May 18, said that the increased cost of labour and shorter working hours had greatly augmented manufacturing and distributing expenses, and that it would be impossible to maintain present wages and hours unless output and efficiency could be increased or more mechanical work adopted. Already the directors had considered the advisability of closing down certain departments in the factories, as foreign manufactured oil, margarine, etc., could be bought at lower prices than they could be manufactured in this country. The best "Maypole" margarine was now being retailed at 8d. per lb., compared with 1s. 1d. in December last. There had been a large increase in turnover during the past year, but the profit was less than 3 per cent. on the value of the goods sold—£36,500,000. The difficulties of trading when market values were constantly changing was illustrated by the necessity of having to purchase and carry at least 30,000 tons of crude oil three to six months before it could be delivered. During last year the price of crude oil fell from £100 to £70 per ton and the decrease in value would have seriously affected last year's results had it not been possible to reclaim some of the excess profits duty paid in recent years.

FANTI CONSOLIDATED MINES, LTD.—In his address at the annual meeting held on May 12, Mr. Edmund Davis, chairman, said that it had been decided to expend £250,000 in developing and equipping the company's manganese proposition in West Africa, and that a contract had been entered into for the sale of 500,000 tons of ore at a guaranteed minimum profit of 7s. 6d. per ton. Although no washing-plant had yet been erected, 85·4 per cent. of the output had averaged 49 per cent. or over of manganese. Development work during the past year indicated that previous estimates of the extent of the ore deposits were likely to be exceeded. In his opinion the manganese deposits, which were valued in the company's books at £1000, were worth the entire capital of the company (£540,000).

NEW CAPITAL ISSUES.—*Brunner, Mond and Co., Ltd.*—The issue at par of 2½ million 7½ per cent. cumulative preference shares of £1 each was quickly oversubscribed and the shares quoted at a premium. The money provided by this issue will be used to repay advances towards the construction of large works now being erected for the manufacture of soda ash at Wallerscote, near Winnington, for the nitrogen works at Billingham, Stockton-on-Tees, for workmen's houses, and for further working capital.

The United Glass Bottle Manufacturers, Ltd., has offered £600,000 seven per cent. first mortgage debenture stock (free of income tax up to 6s. in the £) at par; the proceeds of the issue will be spent on constructional work at the Charlton factory, etc.

LEGAL INTELLIGENCE.

CUSTOMS SEIZURE OF PYROGALLIC ACID. *Attorney-General v. Brown.*

In the Court of Appeal on May 10, Lords Justices Bankes, Warrington and Scrutton by consent allowed an appeal (upon terms not stated) by the Crown against a judgment of Mr. Justice Sankey delivered on December 7, 1919 (*cf.* J., 1919, 481 R). The suit was by the Crown, by information, for the condemnation of six packages of pyrogallic acid consigned to and imported into Manchester by the defendant, Mr. John Brown, trading as Brown and Forth, chemical manufacturers, of Manchester and London. The goods were seized on August 29, 1919, under a Proclamation dated June 25, 1919. Mr. Justice Sankey held that the Proclamation was illegal and invalid and entered judgment for the defendant with costs.

The Attorney-General now stated that the case was met by Section 4 of the Indemnity Act, 1920, and counsel for the defendant intimated that he could not contest that proposition.

DISPUTE OVER ZINC-OXIDE RECOVERY PLANT. *Keeling and Walker, Ltd. v. The Sturtevant Engineering Co., Ltd.*

In the Court of Appeal on May 9 and 10, before Lords Justices Bankes, Scrutton, and Warrington, Messrs. Keeling and Walker, Ltd., chemical manufacturers, appealed against an order of the King's Bench Divisional Court and a judgment of the Official Referee disallowing their claims against Messrs. The Sturtevant Engineering Co., Ltd., of London, for damages for the alleged failure of a zinc-oxide recovery plant supplied by them (*cf.* J., 1920, 403 R).

Counsel for the appellants stated that the respondents claimed that the contract was merely for the sale of goods, but his clients contended that it was also for design and labour, and these could not be taken back. For the respondents it was admitted that they had to return the purchase price, but as the appellants had cut up the cooling-plant there should be some deduction on that account.

In giving judgment, Lord Justice Bankes held that the Official Referee was right in taking the view that the respondent company was entitled to succeed. The Divisional Court agreed with that view, but referred the matter back to the Official Referee, as there was more than one contract and different considerations might apply to the cooling plant. The respondent company had taken back the suction plant and was therefore under no obligation to pay damages, but it must return the purchase price. The judgment of the Official Referee would stand in respect of the suction plant, but if the parties could not come to an agreement as regards the cooling plant, the matter must go to the Official Referee.

REPORTS.

REPORT ON THE ECONOMIC, FINANCIAL, AND INDUSTRIAL CONDITIONS OF FINLAND IN 1920. *By* C. H. MACKIE, *H.M. Consul, Helsingfors. Department of Overseas Trade. Pp.* 44. *London: H.M. Stationery Office.* 1921. *Price* 1s. *net.*

Finland was declared an independent sovereign State in December, 1917, and a Republic in July, 1919, and it was only after the latter event that the country began to recover economically. The progress made has been marvellous. With a total population of only 3,331,814 (January, 1919), mostly engaged in agriculture, Finland is one of the most prosperous of the smaller European States, a position which it owes mainly to the timber and pulp and paper industries (*cf.* J., 1921, 71 R). The latter made good progress in 1920 (figures of production for the whole year are not yet available), but the trade in timber was chequered. All business was adversely affected by the fluctuating rate of exchange; the official rate in London varied between 65·70 Finnish marks to the £ in March to 180 marks at the end of November, the average rate being about 102 marks (par value 22·25 mk.). Rapid progress is reported in the leather industry, which now comprises 26 tanneries and eight shoe factories. In spite of restrictions on imports and depreciated exchange, hides were imported to the value of 70 million Finnish marks. Among new developments to be noted are the erection by the Government of a sulphuric acid and superphosphate factory at Kotka, with a capacity of 20,000 t. of superphosphate per annum; the rebuilding of the Kotka cellulose factory for the manufacture of easy-bleaching sulphate pulp; a paper mill with an output of 12,000 t. of strong wrapping paper has been completed at Björneborg, and at the same place a sulphite-pulp mill capable of producing 14,000 t. of pulp per annum is nearing completion. A large hydro-electric station is being built at Aetsa to supply about 7000 h.p. to the industrial establishments at Björneborg, some 70 km. distant.

The import and export statistics given in the report cover the first nine months of the year. During this period Germany supplied the bulk of the dyes and colours and had rather more of the trade in drugs and chemicals than had Great Britain, but the United States had the greatest share of this trade. Great Britain was the largest

supplier of gums, asphalt, resin, rubber, hides, minerals and manufactures thereof, perfumery, textiles, thread, and twine. Sweden, Germany, and the United States are our chief competitors, Sweden supplying mainly metals, enamelware, and machinery, and the United States chiefly oils and fats, machinery, gums, asphalt, etc., and hides.

A summary of the trade returns for the whole of 1920 is given in the *Board of Trade Journal* for March 24. These show that although imports still exceeded exports the position in this respect has very much improved. The following are the values in millions of Finnish marks:—

	Imports. 1920.	Exports. 1920.
Total for the year	3620·4	2906·6
Chemicals and drugs	169·5	1·2
Colours, etc.	43·9	0·2
Explosives	9·3	19·4
Fertilisers	21·4	—
Ether, alcohol, etc.	5·3	2·6
Oils, fats and waxes	197·0	1 5
Asphalt, tar, resin, rubber, etc.	81·7	6·5
Minerals and their products	156·5	5·0
Metals and manufactures	529·8	4·8
Skins, furs, leather	121·9	38·1
Paper pulp, cardboard, etc.	6·3	1080·7
Wood and wooden goods	16·0	1633·4

Further statistics supplied by H.M. Consul show that Great Britain headed the list in the import trade with about 28 per cent., the United States was second with about 21 per cent., followed by Germany with 17, and Sweden with 10 per cent. respectively. The United Kingdom's share of the Finnish export trade was 43 per cent.

THIRTY-EIGHTH REPORT OF THE COMPTROLLER-GENERAL OF PATENTS, DESIGNS, AND TRADE MARKS, 1920. *London: H.M. Stationery Office.* 1921. *Price 2d. net.*

The volume of business done by the Patent Office during 1920 again showed a substantial increase, though not to the same extent as in 1919 (*cf.* J., 1920, 292 R), the total number of patent applications filed being 36,672, or 3819 more than in 1919, when the increase amounted to 11,014. Although more patent applications were filed than in any other year, a considerable proportion of the increase was due to the many foreign applications made under the Peace Treaties. Thus, Convention applications made under the extensions of time granted by the Peace Treaties and the Berne Agreement of June 30, 1920, were largely responsible for the increase of 49 per cent. in the number of complete specifications filed on application; the number of complete specifications filed after provisional specifications decreased slightly. Designs applications numbered only 13,669, or 425 less than in 1919, but trade-mark applications, with a total of 14,064, showed a gain of 1585, and were well above the pre-war level. There was a further substantial increase in the business transacted; 263,000 letters and correspondence forms and 92,000 parcels of publications were dispatched, and 260,368 patent specifications sold.

The number of hearings upon oppositions to the grant of patents was 43, and there were seven appeals to the Law Officer; 1550 hearings were given under Sections 7 and 8 of the Acts, with three appeals to the Law Officer.

Altogether 120,512 readers made use of the Library, the increase of 21,894 possibly being due to some extent to the extension of the hours to 9 p.m. The Library, which was being re-classified, contained 59,394 works (183,675 volumes, exclusive of duplicates).

The sum of £420,472 was received for patents fees (renewals £277,500), and £8690 and £39,295, respectively, for designs and trade-marks fees. Total receipts amounted to £487,543 8s. 9d. and total expenditure to £401,036, the balance representing about 18 per cent. of the total receipts.

TRADE NOTES.

BRITISH.

The Fertiliser Trade in South Africa.—The use of fertilisers in South Africa was steadily increasing until conditions arising out of the war greatly reduced importation. The decline in importation is illustrated in the appended table, which gives the imports in 1913 and 1919, and the percentages supplied by the chief countries of origin:—

	1913. Long tons.	1913. Per cent.	1919. Long tons.	1919. Per cent.
Basic slag	5,330	Ger. 43, Belg. 22, Holl. 21, U.K. 14	1,714	Holl. 100
Bone fertilisers	4,209	Ger. 27, Ind. 22, U.K. 21, Holl. 14, Russ. 12	112	Arg. 87, Ind. 8, U.K. 2
Guano	313	Seychelles 73, U.K. 15	1,778	S.W. Protect. 76, Falk. Is. 23
Nitrate of soda	65	Ger. 61, Chile 31	—	—
Phosphate, raw	680	Ger. 68, U.K. 20, Belg. 8	5,852	Egypt 96, S.W. Protect. 4
Potash fertilisers	1,739	Ger. 78, U.K. 7, Ind. 6	406(lb.)	U.K. 100
Sulphate of ammonia	366	U.K. 92, Ger. 8	—	—
Superphosphates	36,619	Holl. 66, Ger. 19, U.K. 7	740	U.K. 100
Whale manures	—	—	9,056	Falk. Is. 100
Other fertilisers	7,665	U.K. 51, Holl. 35, Ger. 11	13	Nor. 45, Swed. 41, U.K. 14

The fertilising constituents required by South African soils are, in order of importance, phosphoric acid, lime, nitrogen, potash.—(*U.S. Com. Rep., Mar.* 18, 1921.)

Sierra Leone in 1919.—Although the trade of this Colony was satisfactory in 1919 and showed signs of expansion, there was much distress among the inhabitants owing to the shortage of food and the increased prices of imported goods. Towards the end of the year conditions improved owing to better prices being obtained for palm kernels and palm oil, which were produced and exported in much larger quantities than in former years. The crop of kola nuts was also larger, and the higher prices obtainable in Europe for piassava caused this commodity to be shipped in larger quantities, although the actual export is almost insignificant in comparison with the vast amount of raw material available. The gum copal reserve in the Kessewe Hills and four areas in the Ronietta district were opened to gum collectors during the year. So far as is known the mineral resources of Sierra Leone are very small; there are, however, deposits of laterite iron ores which would be valuable if a process for treating titaniferous iron ores were available. Various products of the Colony were examined by the Imperial Institute. Po-yak nuts (*Parinarium* sp.) were found to yield a drying oil similar in value to tung oil, and a meal with a lower protein content than is usual in oilseed residues; both nuts and oil should be readily saleable in the United Kingdom. Rowe fibre was also examined, and reported to be very coarse, harsh, interlaced, and only suitable for making heavy-sized yarns or coarse string and rope. Imports were valued at £2,034,780 and exports at £2,101,569, both showing large increases over the preceding year. The chief exports were:—Palm kernels, 50,622 tons; palm oil, 828,750 galls.; kola nuts, 2995 t.; ginger, 1069 t.; and piassava, 1059 t.—(*Col. Rep.-Ann., No.* 1065, *Mar.*, 1921.)

FOREIGN.

The Dutch Oleomargarine Trade in 1920.—Despite the general trade depression and wide variations in prices, the exports of margarine from Holland

during 1920 showed a notable increase, much of which was due to the development of new markets. The anticipated increase in trade with Germany did not materialise, but Great Britain took very much more of the output than formerly. The exports of oleomargarine and butter substitutes in 1919 and 1920 were 53,881 and 92,883 metric tons, respectively, the percentages taken by the principal consumers during the two years being as follows:—United Kingdom, 48 and 55; Germany, 46 and 33; Belgium, 4 and 2; Czechoslovakia, 5 (1920 only). The raw materials are obtained mainly from the United States or through firms in other countries which are controlled by American capital.—(*U.S. Com. Rep., Mar.* 24, 1921.)

REVIEWS.

LEHRBUCH DER FARBENCHEMIE. *By* DR. HANS. TH. BUCHERER. *Second edition, revised. Pp. xii.+* 636. (*Leipzig: Otto Spamer.* 1921.) *Prices: unbound* 47*s.* 1*d.*, *bound* 51*s.*

It is a far cry from Dr. Bucherer's modest little booklet of 1904 in the "Sammlung Göschen" to the present imposing volume, but it indicates that the lines originally laid down by the author have proved to be sound under the test of experience. The second edition of Prof. Bucherer's larger work differs but little from the original 1914 edition except that it is slightly longer (636 as against 557 pages), whilst the text has been revised and some new matter added, but all the excellent features which distinguished the former edition are retained, so that the text-book still remains one of the best of its kind for students of colour technology. The section dealing with the anthocyans is entirely new, but in spite of the large amount of work done by English chemists on this class of colouring matters, almost the only name mentioned is that of Willstätter, and the same tendency to ignore the work of non-Teutonic chemists is noticeable in the "Literatur Verzeichnis" (on pp. 602—636), by means of which the author has sought—though not very successfully—to meet the objection that no literature references were given in the first edition to enable the student to follow up any matter of special interest.

One cannot help feeling that the authors of German works on organic chemistry must sometimes be in the habit of saying to themselves "Organic chemistry is a German Science, founded by Liebig of immortal memory," and accordingly ignoring so far as possible the work of all scientists west of the Rhine. This tendency is also noticeable in the section on the cyanine and other sensitising dyes, where the important work of English and American chemists on the subject such as Adams, Mills, Wise and others is altogether disregarded, with the result that several of the formulæ quoted by Bucherer stand in need of revision in the light of the most recent research. The list of references already noted is a step in the right direction, but still needs considerable improvement before it can be regarded as satisfactory.

The statement on p. 493 apropos of the decrease in the acreage under indigo cultivation in India during 1916–18 is illuminating:—"Die mit Indigo bebaute Fläche nahm in ganz auffallendem Masse ab, offenbar vor allem infolge der grossen, durch den U-Boot Krieg verursachten Schwierigkeiten, den Farbstoff über See zu verfrachten." We are afraid these lines were penned whilst the eminent German author was still feeling the after-effects of "U-Boot Fieber," and that he will find the cause of the decrease to be a good deal nearer home, say, in the neighbourhood of Ellesmere Port!

In the chapter on the Natural Dyes the recent work of Dimroth and his pupils on carminic and laccaic acids is discussed, but no mention is made of von Lampe's synthesis of Curcumin in 1918 in the section dealing with that colouring matter.

The addition of marginal rubrics makes the second edition somewhat handier than its predecessor, but the use of italics or other distinctive type for sectional sub-headings would be a great advantage. Most of the defects noted are, however, but slight, and the second edition cannot but enhance the reputation already won by the 1914 edition.

F. A. MASON.

ANTHRACENE AND ANTHRAQUINONE. *By* E. DE BARRY BARNETT. *Pp.* 436. (*London: Baillière, Tindall and Cox.* 1921.) *Price* 27*s.* 6*d. net.*

Since the publication, many years ago, of Auerbach's "Anthracen" (1880), a work which is probably unknown to the younger chemists of the present day, no attempt has been hitherto made to collect in book-form an account of the varied reactions of this hydrocarbon and its derivatives. In the interim an extraordinary amount of new matter has accumulated on this subject, much of which is only to be found interspersed among the foreign patent literature, not easy of access to the average student and, moreover, involving search of a tedious character. The appearance of Mr. Barnett's book is thus greatly to be welcomed, and this should prove to be of much service not only to colour chemists, but to students of organic chemistry in general. The volume of approximately 400 pages is divided into eighteen chapters:—I. Introduction; II. Anthracene and its Homologues; III. Simple Anthracene Derivatives; IV. The Anthraquinones and Dianthraquinonyls; V. Anthrone, Anthranol and Allied Products; VI. Anthraquinone Ring Syntheses; VII. The Benzanthraquinones; VIII. The Aldehydes, Ketones and Carboxylic Acids; IX. The Nitro, Nitroso and Halogen Anthraquinones; X. The Sulphonic Acids, Mercaptans and Sulphides; XI. The Amino Anthraquinones and Dianthraquinonylamines; XII. The Hydroxy and Amino Anthraquinones and Ethers; XIII. Pyridine and Quinoline Derivatives; XIV. The Acridones, Xanthones and Thioxanthones; XV. The Benzanthrones; XVI. The Cyclic Azines and Hydroazines; XVII. Miscellaneous Heterocyclic Compounds; XVIII. Miscellaneous Compounds; and there are, in addition, addenda and an index of German patents.

The book contains a very large amount of information from the scientific aspect which is well arranged and has without doubt involved considerable labour on the part of the author. On the other hand, one feels that the subject matter is, if anything, of too condensed a character, and might perhaps be more easily assimilated had it been spread over two volumes of about the present size. It appears a pity that in a work of such importance but four and a half pages are devoted to a historical sketch of the subject, and that more attention is not given to the earlier history of the synthetical manufacture of alizarin. References to Schultz and Auerbach hardly meet the case (and, indeed, is not the latter out of print?), for these authors are not entirely unbiased and do not inform one that the successful production of the Alizarin Reds was carried out in this country by Perkin by the dichloranthracene method (a process not alluded to by the author) for some time before they were economically obtained in Germany. Again justice is hardly meted out to the latter, there being no mention of his discovery of anthrapurpurine, 4-amino-alizarin, bromo-alizarin, or of his work on anthraflavic acid and the dibromanthraquinones. Though the book will be found useful for purposes

of reference and, indeed, contains an account of the more recently discovered reactions of importance, there are one or two minor omissions, such as, for instance, the hydroxyanthraquinone-β-carboxylic acids, β-methyl alizarin, anthraquinone oxide, etc., though this may perhaps well be the case when there has been so large an amount of material for collection. The statement on page 253 that anthraquinone sulphonic acid on fusion with alkali gives an alizarin containing as impurity higher hydroxylated anthraquinones is hardly correct, as the commercial dyestuff carefully prepared from the β-monosulphonic acid salt contains only alizarin as colouring matter. Again (page 254), though a pure alizarin can be prepared by the alkali fusion of anthraquinone according to the patented methods, it is easy also in this case, if due precautions be not taken, to obtain it contaminated with higher hydroxylated products. It is difficult to see that the employment by the author of his modification of Pfaff's system of notation throughout the book is of advantage, for this does not economise space, and is only likely to confuse the less experienced reader. Frequently, again, these formulæ, as for instance on page 318, give one the impression of pentavalent carbon, and it is difficult to understand why α β compounds of this and allied types should be represented by diagonal lines, whereas with the ββ derivatives parallel bonds clearly indicating tetravalent carbon should be used (p. 317).

Reference to German patent numbers are naturally numerous throughout this work, but it would have been a greater boon to the student had these been either supplemented or replaced by statements as to the volume and page where they occur in Friedländer.

The book is well up to date, bears evidence of careful search by the author, and should prove of assistance to many investigators. It is, however, sad to see among the enormous variety of facts it contains how few have emanated from work carried out in our own country.

A. G. Perkin.

Silica and the Silicates. *By* J. A. Audley. *Industrial Chemistry Series, edited by* S. Rideal. *Pp. xiv.+374. (London: Baillière, Tindall, and Cox.* 1921.) *Price* 15*s. net.*

Students on being introduced to the consideration of the industrial applications of silicate chemistry often ask to be directed to some suitable book in English dealing with the subject, and it is not easy to comply with the request. It is possible to recommend works giving descriptions of manufacturing processes, but none which, at the same time, emphasises clearly the underlying scientific principles. The title of the book under review raised hopes that this gap in the literature of silicate chemistry might be bridged, for it immediately suggested parallelism with H. le Chatelier's "La Silice et les Silicates." But although the author has drawn on his experience as a ceramic chemist, and on a great accumulation of knowledge, he does not write with the scientific insight and confidence of an investigator nor with any great insistence upon essentials.

The book is divided into six sections, the first dealing with the various modifications of silica, their natural occurrence and artificial production. It is rather surprising to find the regions of stability of the different forms of silica discussed without any reference to the well-known and comparatively recent work of Fenner on this subject, particularly as space is found to mention several old investigations on the artificial production of quartz crystals. At present the stability ranges of the various modifications of silica are debated keenly. They are by no means definitely established, and the subject calls for very careful treatment if confusion is to be avoided. We find it stated:—

(1) Without any qualification that "tridymite is the stable variety of silica above 1500° C." (p. 36);

(2) that "the temperature is about 1600° C. where the transformation into tridymite takes place" (p. 33);

(3) that cristobalite "thus differs from tridymite both by its birefringence and its point of transformation 400° higher" (p. 34); and

(4) that "Tridymite is not known to be formed under any conditions above 1470° C."

The reader must take his choice. A reference on p. 42 to the impossibility of determining by means of optical investigation whether silica obtained from calcining hydrated silica is crystalline or amorphous might be brought up to date by mentioning the possibility of settling this point by the X-ray method of crystal analysis of powders. Kyropoulous has concluded in this way that amorphous silica shows no evidence of regular, internal structure, but after calcination at 1300° C. the interference bands characteristic of cristobalite appear.

The properties and uses of natural and artificial silicates are discussed in the next part, whilst the third section is devoted to lime, cement, and mortar. Good descriptions of the manufacturing processes are given, but a fuller reference in the text to the diagrams of the various plants would be useful to many readers who are unfamiliar with the industry. This is also true of other sections of the book, almost a complete page being devoted, for example, to diagrams of the Stein tank furnace with no specific reference to it in the text.

The fourth section deals with the ceramic industries, and a very readable account is given of pottery and brick manufacture, together with passing references to more special non-silicious refractories. The earlier remarks with regard to the subordination of the scientific aspect of the subject are illustrated in this section. For example, in a discussion of the fusibility of clays no reference is made to Raoult's law, eutectic mixtures, or to Ludwig's work on this question.

Section five discusses glass and enamels, and considers the raw materials, the composition and properties of various types of glass and enamels, glass furnaces, etc. The last section is devoted to some miscellaneous applications of silicates.

The descriptions of methods of manufacture are clear and concise, and the book will be of use without completely satisfying the demand for an English text-book giving a scientific exposition of the silicate industries. The conclusions of many investigators whose work has appeared in recent years in the journals of the English and American Ceramic Societies and the Society of Glass Technology are summarised. This feature of the book will be very valuable to those who have not the time or opportunity to consult these journals. The references to the results of continental workers are not so numerous. Both the text of the book and the diagrams are well produced, and short bibliographies are given at the end of each section and at the end of the book.

Summarising, this work is full—even crowded—with information both as to the occurrence and properties of raw materials and as to manufacturing processes. It gives also the results obtained by many investigators on many branches of the subject. It loses grip, as do so many technological and scientific books of the present day, by overlaying essentials with more or less relevant detail and in refusing to select or decide—a method of treatment which has both advantages and disadvantages, but is more informing than stimulating.

John W. Cobb.

OBITUARY.

BERTRAM BLOUNT.

The death of Bertram Blount on April 9, at the age of 54, has removed a well-known member of the chemical profession and of this Society. Educated at King's College, London, under C. L. Bloxam, he started practice with W. H. Stanger, and continued independently when that partnership was dissolved. He devoted himself more especially to engineering chemistry, and in collaboration with A. G. Bloxam published a book on "Chemistry for Engineers and Manufacturers," whilst his individual publications "Cement" and "Practical Electrochemistry" are also well known. On both these subjects he was a widely-recognised authority, and at the time of his death he was editing a series of books on Electrochemistry, two volumes of which have been already published. He was also the author of papers on the "Determination of Oxygen in Commercial Copper," "Vacuum Balance Cases," "The Limitations of the Balance," and other subjects. Blount enjoyed an extensive consulting practice, and was frequently called as an expert witness in chemical law cases. Of marked individuality and characteristic manner, he was not readily forgotten by those with whom he came in contact, and it is a subject for regret that he should have broken down at so early an age.

EDMUND JAMES MILLS.

Prof. E. J. Mills, who died on April 21 last, was born in London on December 8, 1840. He was educated first at the Grammar School, Cheltenham, and then at the Royal School of Mines, where he took the courses of instruction for a degree in science at London University, at that time the only university in Britain granting such degrees. He graduated B.Sc. in 1863, and obtained the doctorate in 1865. There were few candidates for science degrees at that time, and on looking at the list of graduates it is interesting to note that Mills's name appears about equidistant in time between those of Prof. Alex. Crum Brown, in 1862, and Sir William Tilden, in 1871.

In 1861 Mills became assistant to Dr. John Stenhouse, and a year later was appointed one of the demonstrators in chemistry at Glasgow University, in which capacity he conducted tutorial classes for medical students, a work not very congenial to him, and one which, from his temperament, he was not particularly well fitted; he was, however, a good laboratory teacher for advanced students. He resigned this appointment in 1865. In 1875 Mills became superintendent of the "Young Laboratory," in Anderson's College, Glasgow, and during his term of office, about the year 1886, that foundation, together with Anderson's College, became incorporated in the Glasgow and West of Scotland Technical College, the Young Laboratory appointment being converted into the Young Chair of Technical Chemistry. His predecessors in charge of the Young Laboratory were W. H. Perkin, sen., 1870–71, and G. Bischof, 1871–75.

Mills was the author of many papers covering a wide field of work. Although his first recorded paper in the Proceedings of the Royal Society (1860) is upon brom- and chlor-phenylamine, his early work inclined more to general and inorganic chemistry, dealing with subjects such as isomerism, statical and dynamical ideas on chemistry, chemical equivalents, etc., and this tendency is seen also in his later papers in the Philosophical Magazine, published during 1883, '84, and '87. In the Journal of the Chemical Society his more important papers are:—"On Aniline Derivatives and Nitrotoluene" (1875–76); "On Potable Waters" (1878–81); "On Chemical Repulsion" (1880–81); "Melting-points" (1882). From 1879 to 1882 he published "Researches on Chemical Equivalence"; from 1878 to 1880 papers on "The Action of Oxides on Salts"; and later, "Researches on Dyeing," in conjunction with Louis Campbell. To the Society of Chemical Industry he contributed papers on the "Quantitative Estimation of Oils and Fats" (1883), "Viscosity Determinations" (1886), and "Oxidation of Aniline" (1894). In his books Mills did not confine himself to purely scientific matters, for, in addition to two works, "Fuel and its Applications" (published conjointly with E. J. Rowan in 1889) and "Destructive Distillation" (1892), he wrote a volume of poems "My Only Child" (1895), and "The Secret of Petrarch" (1904).

Mills was elected a Fellow of the Royal Society in 1874, and was an honorary LL.D. of Glasgow University; he was an original member of the Society of Chemical Industry and served on the committee of the Glasgow Section, including two periods as vice-chairman, from 1884 to 1894; and was a member of the Council of the Chemical Society at various times from 1868 to 1906, serving as vice-president from 1912 to 1915. After retiring from his professorship in Glasgow in the early 'nineties, he returned to London and rendered valuable service as a member of the Library Committee of the Chemical Society.

DANGEROUS DRUGS.

As a result of the criticisms which were directed against the draft Regulations issued under the Dangerous Drugs Act (*cf.* J., 1921, 79 R, 139 R), the Home Secretary appointed a Committee to consider the outstanding objections and to advise on modifications. The Report of this Committee, which has just been issued (Cmd. 1307, 3d.), shows that witnesses were heard on behalf of the British Medical Association, the Pharmaceutical Societies of Great Britain and Ireland, the Drug Club, Fine Chemical Manufacturers' Associations, the Central Chamber of Agriculture, the Association of Public Analysts of Scotland, and twenty-four other allied bodies. After consideration of the evidence, the Committee has recommended certain further modifications and additions which it claims will "almost entirely remove" the objections to the original draft.

In our issue of April 30 last we pointed out that the draft Regulations overlooked the fact that the drugs in question were constantly used in chemical, physiological, pharmacological and other laboratories, and that no provision was made for their possession and use by the experts in charge of such institutions. An attempt, which cannot be regarded as completely successful, has been made to remedy this defect in the revised regulations. In Article 11 it is stated that " . . . any person in charge of a laboratory for purposes of research or instruction attached to any university, university college, public hospital or other institution approved by the Secretary of State for the purpose, or any person appointed by a local authority with the approval of the Minister of Health as an analyst for the purposes of the Sale of Foods and Drugs Acts, 1875 to 1907," is authorised to be in possession of and to supply the drugs concerned so far as is necessary for the practice of his profession, but subject always to the provisions laid down in the Regulations. Hence scientific institutions which are not "attached" to a university, university college, or public hospital will apparently need "approval" by the Home Office before they can secure a licence, and the same applies to all independent workers such as analytical, consulting and other professional chemists who are not officially-appointed public analysts. This means that such institutions as the Finsbury Technical College, the Imperial College of Science, the Davy-Faraday Laboratory, and the Lister Institute need "approval" before they can possess and use these drugs for research, and that independent workers like the late Sir W. H. Perkin can only secure such a privilege by attaching themselves to a university or a hospital or by becoming public analysts.

Assuming that no further revision will be made, it is to be hoped that the necessary licences will be readily granted to *all* genuine research workers, and a letter from the Home Secretary to the Parliamentary Committee of this Society seems to suggest that this course will be pursued. In the letter, dated April 27 last, it was stated that the Home Secretary "would be prepared to consider sympathetically all applications for licences thereunder from applicants who require to use the drugs for the purpose of *bona fide* research"; nevertheless, we fail to see the necessity for imposing even such a modified restriction on scientific research and for compelling research workers to submit to the delays and vexations which are invariably associated with applications to Government departments.

There are other considerations which, if of less interest to the majority of our readers, are nevertheless of much importance to our pharmaceutical colleagues.

The Committee could not agree to the request that the requirements of a prescription for the sale of the particular drugs named in the Act should be completely withdrawn, but a list of exemptions has been prepared and inserted as a schedule to the Report. This schedule exempts two well-known and popular remedies—Dover's Powder and gall-and-opium ointment—and fifteen other official and unofficial remedies, none of which, however, is used to any extent in medicine or pharmacy. The Committee ignores the point made by the Pharmaceutical Society that the prohibition is *ultra vires* on the ground that it can only be settled by competent judicial authority. Amendments are proposed to make it clear that dentists, veterinary surgeons, and medical practitioners can administer the drugs to their patients without writing a prescription or keeping a record, and the Pharmaceutical Society's suggestion that the prescription should bear the name and address of the person for whose use it is intended has been adopted. As an attempt to meet various objections from the British Medical Association, the Pharmaceutical Society, and the Drug Club, a new clause has been inserted regarding the marking of packages or bottles containing the specified drugs. Special regulations have been agreed upon concerning the application of the Act to hospitals and similar institutions, but the Committee has been unable to overcome the difficulty that the Regulations do not apply to preparations containing less than 0·2 per cent. of morphine or 0·1 per cent. of cocaine or diamorphine. It was demonstrated that a big bottle containing any one of the drugs specified in the Act of a strength below the limit fixed in the Regulations might actually contain more of the drug than a small bottle of the drug in a concentrated form; so that a person desirous of gratifying the drug habit can avoid the Regulations by purchasing a large bottle of the low strength. The Committee admits its helplessness and states that it cannot be blamed as it did not frame the Act! Again, the Committee fights shy of the submission on behalf of the Pharmaceutical Society (emphasised in a "Reservation" by Mr. W. J. Uglow Woolcock, a member of the Committee, and printed at the end of the Report) that if it is desirable for the protection of the public that a pharmaceutical chemist should be prohibited from dispensing any of these drugs without a medical prescription, it is equally desirable that these drugs should not be dispensed by the doctor who prescribes them.

LIQUID FUEL FOR STEAM-RAISING.

N. A. ANFILOGOFF.

There is no industry in which fuel oil cannot advantageously replace coal as a source of heat or power. In reverberatory furnaces, metallurgical furnaces, for electric-light-filament carbonisers, cement kilns, rivet forges, and even ordinary cooking stoves, fuel oil has been tried and proved to be more efficient than coal.

For steam-raising liquid fuel is, beyond compare, the more efficient fuel of the two. In the Lancashire boiler, for instance, a third of the length of the internal flues is divided in half by the fire-grates, and no heat at all impinges on the lower half. On the contrary, the cold air entering the ash-pit cools the boiler-plate where the layer of ashes does not insulate it. With fuel-oil firing the whole of the area of the circle of the flue is under heat, thus increasing or making more effective the available heating surface and greatly assisting the

water-circulation. The intensely hot flame, which can be easily controlled, gives a more steady head of steam; and it may be asserted that in any factory where four boilers under coal fires can hardly carry the load, three only of these boilers under oil will suffice. This the writer has personally experienced. One must not forget that one man can quite easily look after four boilers under oil, whereas at least three men would be required if these boilers were hand-fired by coal. There is no cleaning of fires, trimming, or wheeling away of ashes with oil-fired boilers.

During the present coal crisis very many factories adopted oil as "the next best thing" at "whatever the cost," quote forgetting or not knowing that, as a matter of fact, they had been losing money, or, at least, failing to make the most economic use of their boiler-plant, by their previous use of coal.

Apart altogether from savings in many other directions, let us examine how the use of coal compares with that of oil. To-day's prices (or rather pre-strike prices) may be taken as 50s. per ton for coal and 90s. per ton for fuel oil. Examining theoretical values as a guide and taking calorific values, we get an average of, say, 14,000 B.Th.U. for coal and, say, 19,000 B.Th.U. for liquid fuel—that is, 1 of oil is equivalent to 1·4 of coal. Taking also theoretical evaporative values, we get, say, an evaporation of 11·8 lb. of water from and at 212° F. for 1 lb. of coal and 17·9 lb. of water from and at 212° F. for 1 lb. of oil, *i.e.*, in this respect 1 lb. of oil is equivalent to 1·5 lb. of coal. In practice, however, working on actual monthly consumption figures, the writer has hardly ever exceeded an evaporation of 8 lb. of water per 1 lb. of coal, and has invariably obtained an evaporation of 15·6 lb. of water per lb. of oil. These actual consumption figures therefore show that 1 lb. of oil will do the work of 1·95 lb. of coal. Translating these figures into cash values on comparative costs of fuel, we find that 1 ton of coal at 50s. evaporating 8 tons of water gives an evaporation-cost of 6s. 3d. per ton of water, whereas oil at 90s. evaporating 15·6 tons of water gives an evaporation-cost of 5s. 9d. per ton of water converted into steam.

Assuming that we are dealing with a factory employing four boilers, each capable of evaporating 7500 lb. of water per hour, we get the following interesting statement of comparative costs:—

Evaporation 72,000 galls. per 24 hours or 321½ t.

Evaporation cost.	Coal.			Evaporation cost.	Oil.		
321½ tons at 6s. 3d.	£100	9	4	321½ tons at 5s. 9d.	£92	8	7
1 Fireman at 2s. ..	2	8	0	1 Fireman	2	8	0
1 Assistant at 1s. 11d.	2	6	0				
1 Trimmer at 1s. 10d.	2	4	0				
	£107	7	4		£94	16	7

Thus there is a clear cash saving of £12 10s. 9d. per day. But without any such saving in cash, the advantages derived from greater efficiency of boiler-plant, ease of control and absence of ash, dust and dirt, in themselves would demand the change from coal to liquid fuel. We are, however, very, very conservative and afraid to make a departure from the methods employed by our fathers and grandfathers.

Speaking to a chemical manufacturer with a large business, the writer was given a reason why the chemical factory was still burning coal that seemed to him to sum up the position—he was told that boilers under coal have lasted 20 years or more, and that no one would come forward to guarantee the life of the boiler under oil. But neither would the boiler-maker guarantee the life of the boiler under coal fires except with the proviso that reasonable care must be taken. Now, in the words "reasonable care" lies also the mystery of success or failure in burning liquid fuel. The work falling on the fireman is so light and the control of the liquid fuel fires so easy, requiring, as it does, the turning of a valve-wheel, that there should be no excuse why the most punctilious care should not be bestowed on the boiler.

On the other hand, with oil fuel the whole of the flues of a Lancashire boiler, or the combustion-chambers of tubular boilers, are under equal heat, doors have not to be opened for stoking up, thus admitting gusts of cold air, so that there is no sudden periodic contraction which, under coal-firing conditions, has added not a little to the reduction of "life" in boilers. No reasonable care, however, can be taken of boilers if the man in charge has not sufficient knowledge to qualify him as a stoker, and the writer envies the works manager or engineer of a U.S.A. factory in this particular. No man there can take charge of a boiler unless he has qualified for and gained a certificate or licence, which has to be framed and exhibited in the boiler-room. In this country, unfortunately, anyone can and does "fire" boilers, but that same anyone absolutely must have a little tuition to fit him to look after oil-fired furnaces.

The difference between coal and oil as fuel lies in the fact that whereas in coal we have a fuel of which some 75 per cent. is burnt slowly on the grate as a solid, in oil we have a fuel the whole of which is burnt quickly as a heavy vapour. In the first case combustion must depend on grate-area, in the latter case it depends on combustion-area.

To get the most efficient results from liquid fuel, one must arrange for two essentials:—(1) The provision of means to convert the oil into a heavy vapour; (2) the provision of sufficient air to support combustion.

To convert the whole of the oil into vapour, as the term is ordinarily understood, would, of course, mean that a boiler or still must be provided in which the oil would be converted into vapour by distillation. This, however, is not necessary, as the oil is burnt in practice *not* as a "vapour," as the chemist understands the word, but rather as a heavy "mist" mechanically created. The instrument used for creating the mist is called the "burner," or "atomiser." The more finely the oil is atomised, the easier it mixes with air, and the easier, therefore, it ignites and burns.

In selecting an atomiser, the intending purchaser is faced with such an array of "systems" and "patent" burners that it is not surprising that he halts bewildered. In this country the best known are the "Wallsend-Howden," "Scarab," "White," "Kermode," "Korting," and "Holden." These are not enumerated in their order of excellence. The trouble is that each system is "the best," and the advocates of each insist on the installation of their *whole* system as absolutely necessary to achieve efficiency. Much nonsense is incidentally made use of further to bewilder the intending purchaser. One or other of the salesmen will impress you that in his system provision is made for superheating the air, which saves fuel and gives better combustion. Of course, air cannot be superheated. It is true that a slight preheating of the air aids the rapidity of combustion, but to use furnace heat, for instance, to preheat the air, and then to return that heat back to the furnace can only be purposeless transfer of heat (minus losses). It can accomplish nothing and can create nothing, just as stirring water cannot increase its quantity.

Then, again, some urge that their burners must work at a certain pressure, and that the oil must be at a certain temperature. This is also nonsense. There is no burner which will work equally well with any oil at fixed pressures and temperatures; so much depends on the composition and viscosity of the fuel itself. In the main there are two systems:—(1) That in which the oil under pressure is

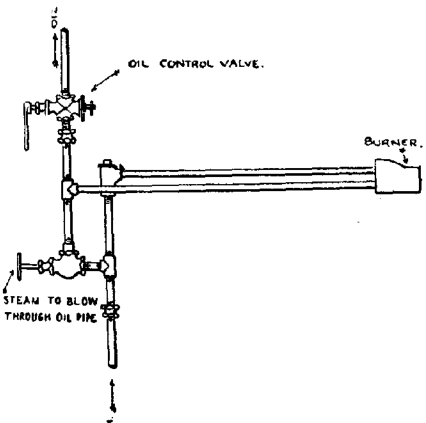
conveyed by more or less tortuous paths to the burner-tip, where it impinges on an obstruction and is forced through a small aperture which causes it to break up into a more or less fine spray; and (2) the system in which the oil is atomised by a stream of air or steam.

On board ship, where water supply is limited, the pressure system is adopted, and for land work, where steam would have to be brought from afar, or where the furnace to be heated is intended for purposes other than steam-raising, the pressure-system would perhaps be the more economical; but for boiler work on land the steam atomiser is by far the easier to handle, the less costly to install, the more efficient from the point of view of smoke-abatement, and certainly not the less efficient thermally.

The installation of the pressure system is very complicated, as it requires a multiplicity of accessories such as filter-chambers, heating chambers, etc., all in duplicate, numerous valves, pipes, and by-passes. The minute orifices in the burner-tip get choked and carbonised, requiring frequent changing, with consequent loss of furnace heat, and the oil used must be of high grade.

In the steam-atomised burner the installation is very simple; any grade of oil can be used, and there are no minute orifices to get choked. But, here, again, there seems to be such a plethora of various "patents" that one perforce has to pause.

There are two kinds of steam-atomisers. In one a stream of oil and a jet of steam meet outside the burner, and the steam, issuing with greater force, carries the oil with it; but to enable the oil to be broken up into a fine spray, a striking-bridge has to be provided inside the furnace against which the mixed stream of oil and steam impinges. These are called "outside mixers" and are more or less efficient according to design, but in atomising consume sometimes as much as 5 to 8 per cent. of the total steam raised.



Burner and Connexions.—Type of "Inside mixer."

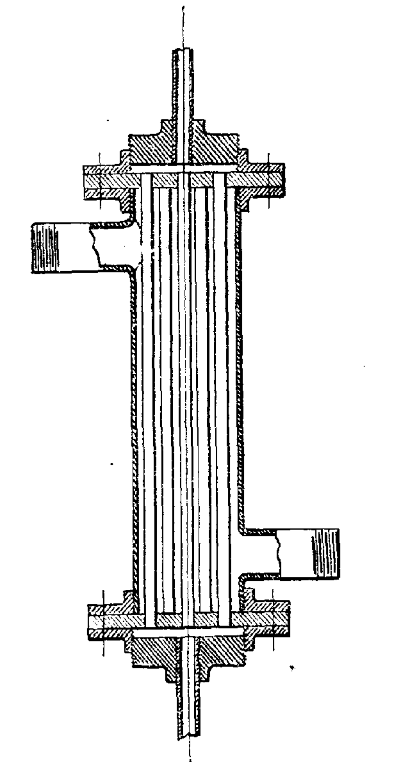
The best-designed burner, in the writer's opinion, is the so-called "inside mixer." In this atomiser the oil is delivered to the burner under pressure. The steam is split up into two channels; one conveys the steam into a small chamber, where it actually mixes with the oil and issues from the burner already mixed; the other channel conveys the remaining portion of steam through a slot beneath the mixing chamber, and on issuing from the burner acts as a guide to the mixture of oil and steam. This burner gives a fish-tail flame, like a gas-burner, and burns comparatively noiselessly. In tests over lengthy periods (not a two- or three-hourly test under favourable conditions) the writer has obtained in actual practice thermal efficiencies varying from 79 to 84 per cent., and a steam-consumption for atomising purposes varying, according to load, from 3·0 to 1·9 per cent.

For efficient combustion of liquid fuel sufficient air is, of course, necessary, but one often meets with an insatiable desire to burn liquid fuel absolutely smokelessly. This is a mistake; it is only achieved by using an excess of air. As it is difficult to gauge when just enough air is being used for complete combustion, it is safer to go just short of perfection and allow a haze of smoke to issue from the chimney than to risk an excessive supply of air, with its attendant cooling, unequal distribution of heat in the combustion chamber, and oxidation of boiler plates and burning out of tubes. The writer has a rough and ready formula for calculating the quantity of air required for complete combustion, viz., by dividing the calorific value of the fuel in B.Th.U. by 100, thus:—

Coal, having a calorific value of 14,000 B.Th.U., would require 14,000/100=140 cb. ft. of air per lb. of fuel.

Oil, with a calorific value of 19,000 B.Th.U., would require 19,000/100=190 cb. ft. of air per lb. of fuel.

These quantities do not fall far short of theoretical requirements and are as nearly as possible actual requirements in practice.



Home-made Oil-heater.
Scale 1½ inches to 1 foot.

Various text-books and system catalogues show illustrations and describe the necessary firebrick

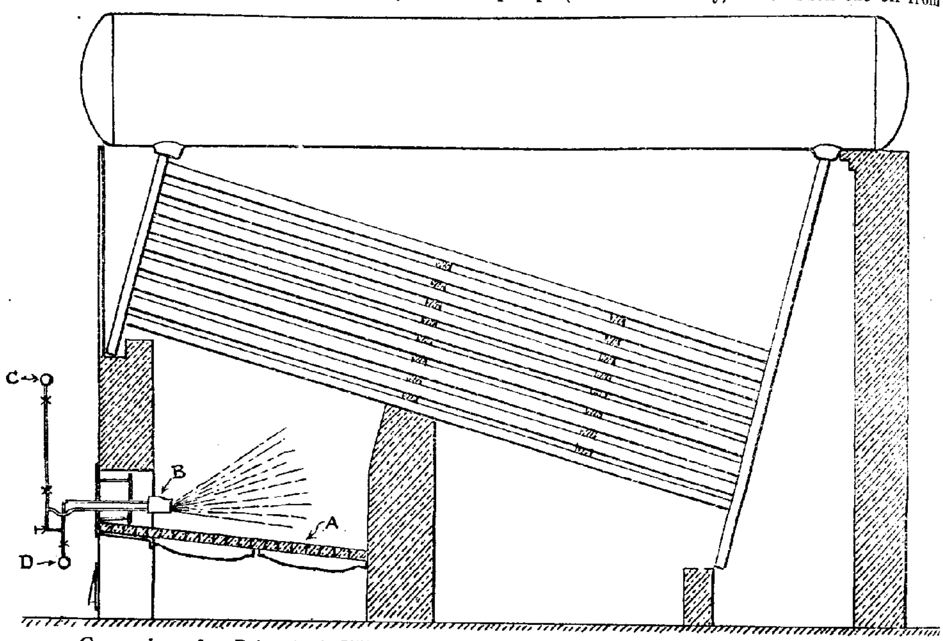
linings and chequer walls in flues of boilers; the writer has never found them either necessary or even mildly useful.

In a Lancashire boiler (except for the striking-bridge required by some atomisers) no firebrick liners are used by the writer, and in the refinery at Thames Haven boilers are at work night and day for six months at a period. After all, the less obstruction there is in the flue the easier does the heat reach the boiler-plate, and the quicker is it conveyed to the water on the other side of the plate.

The Lancashire boiler is converted to oil by taking out the fire-bars, replacing the fire-door by a circular plate through which the burner is inserted, and by providing in the front plate a hinged damper (like an ash-pit damper). A circular cast-iron plate some 3 to 4 in. inside the front plate, or a firebrick wall with chequered bricks (to admit air) is also advisable, as it keeps the flame from buckling the front plate and slightly preheats the air required for combustion. The burner itself, with its injector-action, draws in nearly all the air required. The conversion from coal to oil or *vice versâ* can thus be effected in one hour at a cost of a few shillings, once the installation is fitted.

In a water-tube boiler of the Babcock and Wilcox type the bars can be left in and covered with firebricks laid flat and dry, *i.e.*, no fireclay is used. The furnace-door is replaced by a plate through which the burner can be inserted, a firebrick wall being built up inside the outer front plate with sight- and burner-holes left open. Air is admitted through the burner-opening and by the ash-pit dampers. The air coming up between the loose bricks lifts the flame off the floor, and high efficiency is obtained.

The "System" itself consists of two small duplex pumps (one as a standby) which suck the oil from the tank and deliver it to the burner. In the suction pipe is inserted a gauze filter in duplicate, and in the delivery pipe a small tubular heater. This is heated by the exhaust-steam from the pump. The pump is also provided with a relief-valve which keeps the charge-line at any desired constant pressure. In the steam-delivery to the burner it is well to provide a valve to enable the oil-ducts to be blown-through with steam before being temporarily shut down, or to clear off any oil which might car-



Conversion of a Babcock & Wilcox Boiler to Oil Fuel without alteration of Brickwork.

bonise on the burner tip. It is also wise to provide settling tanks if the oil contains moisture.

To start the boiler from cold, where steam from another boiler is not available, compressed air would be required both to drive the pump and to act as atomiser. This can, of course, be obtained from a small power-driven air-pump or from a storage-cylinder.

When selecting a "System" do not be trapped by claims of "making something out of nothing." Select the simplest. The only desideratum in design should be to develop every heat unit in the fuel and to convey that heat to the boiler with the minimum of loss and without damage to the boiler.

With reference to the oil, it is well to remember that it should (1) have a flash-point (closed test) not less than 150° F., (2) be sufficiently fluid to be pumped at all temperatures (the specific gravity is not always an indicator of viscosity), (3) not contain more than 1 per cent. of moisture, and (4) be free from solid particles of carbon or other extraneous matter which would unduly choke the filter.

Other points of a more general character are:—The boiler-house should be kept clean. There should be no leaks in the oil-pipes of the system. Trays and save-alls should be provided under the pumps and strainers. No oil should be allowed to lie on the floor. Lighted torches should be extinguished before they are thrown on the floor. A water-hose and a sand-box should be provided in each boiler-room. Finally, it must always be remembered that oil heated to or above its flash-point gives off inflammable vapour precisely as petrol does at ordinary temperatures.

SOCIETY OF CHEMICAL INDUSTRY.

JUNE MEETING OF COUNCIL.

Owing to the difficulties of railway travelling no meeting was held in May, matters of urgency being dealt with by a special committee appointed for the purpose.

The Council meeting was held on June 3, Sir William J. Pope presiding.

In view of the impending Annual Meeting in Canada the Council had requested the Canadian Sections to suggest one of their members for nomination to the office of president for 1921–22. The Sections proposed Prof. R. F. Ruttan, Director of the Chemistry Department, McGill University, Montreal, and the Council nominated him for election at the Annual General Meeting.

Four vice-presidents retire from office this year (*cf.* J., 1921, 144 R). The retiring president, Sir William J. Pope, becomes a vice-president, and the Council nominated Mr. J. L. Baker, Mr. C. S. Garland, and Mr. Max Muspratt to the three remaining vacancies. Mr. W. J. U. Woolcock was elected an ordinary member of Council, in place of Mr. W. J. A. Butterfield resigned, for the period ending with the close of the Annual Meeting, 1921; he is, however, eligible for re-election at that meeting. Mr. E. V. Evans was reappointed hon. treasurer, and Prof. H. Louis hon. foreign secretary. It was intimated that June 15 is the last day for receiving nominations of ordinary members of Council.

The balance-sheet and statement of expenditure and income for 1920 were submitted, together with the certificate of the auditors, and these will be published in the issue of the Journal for June 30. Advance copies of the programme of the meetings of the Society to be held in Canada and the United States were laid on the table; copies will be sent to members as soon as a sufficient supply has been received.

It was decided to hold the Annual Dinner of the Society in London early in October; the date and place will be announced as soon as possible.

Forty new members have been elected since the April meeting of Council. The next meeting will be held on Friday, July 15.

ANNUAL MEETING, 1921.

NICKEL PRODUCTION IN CANADA.

During the past three years, despite the many difficulties arising from the abnormal conditions due to the war and its aftermath, a large and important mining and metallurgical enterprise, complete in every detail, has been developed in Canada. The British America Nickel Corporation (through whose courtesy the following information has been made available) has designed and erected mine and smelter plants near Sudbury, Ontario, and a refinery near Ottawa.

The mines owned by the company occupy over 12,000 acres in the mineral-bearing zone, their present activities being confined to the Murray Mine, which so far discloses 16 million tons of ore averaging from 3 to 4 per cent. nickel and copper, sufficient to keep the plants running for 30 years; but the ore body undoubtedly extends much beyond the present operations. In addition to nickel and copper the ore also carries small but valuable amounts of the metals of the platinum group.

The mine plant is thoroughly up-to-date and is furnished with an ample supply of electric power. In the smelter building there are two large blast furnaces in operation with a third in reserve, each having a capacity of over 800 tons of ore per day. The ore, averaging 24 per cent. silica, 35 per cent. iron, 6 per cent. alumina, 3·7 per cent. lime, 4·3 per cent. magnesia, and 19 per cent. sulphur, is smelted without any preliminary roasting. The flux, being converter slag, contains 16 per cent. silica, 52 per cent. iron, 3·5 per cent. lime, and 3·5 per cent. alumina. The charge consists of 70 to 75 per cent. ore, the balance being flux; 10·5 per cent. coke is used with the charge. The resulting slag contains from 0·24 to 0·34 per cent. nickel, iron and copper, together. The low-grade matte, containing about 12 per cent. nickel and copper, is blown in a converter, and the metal content raised to 80 per cent.; the product is then transferred to an oil-fired furnace, in running from which, through a strong stream of water, it is granulated, and in this condition is shipped to the refinery.

At the refinery the matte passes through two Wedge roasters, each with 8 hearths. This is followed by leaching with sulphuric acid which dissolves the copper in part, the metal being recovered by plating out in electrolytic tanks. The cathodes are melted down and cast into ingots weighing about 80 lb., about 55 tons of copper being produced per 100 tons of nickel.

The leached matte is then smelted with fluxes in specially designed electric furnaces. Circular carbon electrodes are used and the nickel copper anodes are cast in steel moulds. The anodes then go to the nickel-depositing building, which covers three acres, where most of the nickel is plated out and a large amount of nickel sulphate and nickel-ammonium salts is produced for the nickel-plating industries. The precious metals are contained in the slimes from the dissolved nickel anodes; they are collected, concentrated, and refined in another department, yielding platinum, palladium, iridium, rhodium, and some gold and silver. Economical power, to an almost unlimited extent, is available from the development at the Chaudière Falls.

Members attending the annual meeting will doubtless be interested in visiting this metallurgical plant, which is probably the largest of its kind in the world.

CHEMICAL ENGINEERING GROUP.

The second annual meeting was held in London on May 31, Mr. J. Arthur Reavell, chairman, presiding. The hon. treasurer's report called attention to the necessity for increasing the revenue, as during the past year expenditure had exceeded income by £163, or £13 allowing for the sum of £150 set aside to cover the cost of printing the *Proceedings* for 1920. On the credit side, subscriptions amounted to £449 (from 427 members), donations to £327, the grant from the Society to £150; and the main items of expenditure were printing and stationery £507, clerical assistance £343, special and miscellaneous expenses £161. On the motion of Mr. W. Macnab it was agreed to make a levy of 7s. 6d. per member to clear off the deficit. Mr. H. Talbot, in his report, reviewed the activities of the Group during 1920, special reference being made to the success of the conferences held in Birmingham and Newcastle. The Group had done useful work on sub-committees of the British Engineering Standards Association, had co-operated with the Association of British Chemical Manufacturers, and had assisted in opposing the Civil Engineers' (Registration) Bill, which might have adversely affected the position of chemical engineers. Good progress was being made with the compilation and publication of data sheets.

The chairman, hon. secretary, and hon. treasurer were re-appointed, and the following were elected to fill the four vacancies on the committee:—Messrs. W. Macnab, P. Parrish, H. J. Pooley, S. G. M. Ure.

At the annual dinner which followed, Mr. J. Arthur Reavell gave an address on the future of chemical engineering. The present condition of chemical engineering, he said, was less promising than it was a year ago. The very difficult conditions of to-day render it almost impossible for plant manufacturers to make promises regarding delivery, or to put forward with any degree of confidence proposals for new schemes to be undertaken by users. Further, there was very fierce competition from abroad, and buyers were already turning to Germany and to America for plant which they had bought in this country during the war; differences in the rates of exchange were helping our competitors and damaging us.

The answer to the question: What is the position of our chemical engineering industry under such depressing conditions? was that a Britisher was never more dangerous than when everything seemed perfectly hopeless. As we were getting into that position to-day, our future was not so black as it appeared; with the obstinacy and tenacity of our race we should even now be able to put up a fight for the world's trade that would surprise everyone. The future of our industry was closely bound up with the question of the treatment of "key" industries. The Government must decide once and for all whether it is going to protect such industries, or whether it is going to leave our manufacturers and traders to take care of themselves. Meantime, this uncertainty was holding up business. Personally he thought that unless the nations agreed to general disarmament, certain of our resources, which eventually must be used for our own protection in time of war, would have to be protected during times of peace.

The most serious menace to future progress was the unsettled condition of labour. He was convinced from his own observations that the average workman, realising what the extreme labour policy was leading to, was anxious to return to more normal conditions, and this spirit must be encouraged. Until conditions were stabilised, and capital interested, nothing of moment could be accomplished. It was important that men and groups of men who finance large schemes should co-operate with manufacturers of plant to their mutual profit. The financier, like the manufacturer, looked for the best market for his goods, and it must be a great temptation for him, with the present rate of exchange, to take advantage of foreign purchases. This, however, was no help to either party if in the end the whole country was the poorer because of it. That was one of the most important points that affect the future of our chemical industry. Another important point was ability to put products and plant at competitive prices on the world markets; and in order to minimise cost, there had been of late a rush for standardisation. Standardisation had many great advantages, but it should not be over-estimated. The success of British engineers and chemists had been due to their individuality, so that if the best was to obtained, industrial effort must not be cramped by carrying it too far. If standardisation were largely confined to parts that are in common use, it would be of help in the future of the industry. Efficiency must be encouraged in every direction; rule-of-thumb working must disappear, and properly trained technical staffs must be available to cope with the ever-changing problems that arise. The future of chemical engineering was bound up with the future of the chemist. The duty of chemical engineers was to put into practice the results of the research and the experiments of the chemist, so that originality of thought and research on the right lines were indispensable to success. Every chemical engineer in this country should rally round the Chemical Engineering Group, so as to make it a huge success. The difficulties with which all young people had to contend were being successfully overcome, and with a better mutual understanding and closer co-operation with the parent Society, the future of the Group and of chemical engineering in this country was assured.

NEWS FROM THE SECTIONS.

MONTREAL.

The annual meeting and dinner were held at the Queen's Hotel, Montreal, on April 22. Mr. C. R. Hazen, chairman of the Section presided, and referred to the regretted death of Dr. Henri St. Georges. The hon. secretary, Mr. G. D. McIntyre, stated in his report that the average attendance at the meetings of the past session had been 55 to 60, and that although a number of members had been transferred to the roll of the new Section at Shawinigan Falls, there was considerable room for improvement in this respect. Four new members and 27 associates had joined the Section during the session. The new draft Rules were submitted and referred to a special sub-committee. On the report of the nominating committee the following officers were elected:—Chairman, Mr. W. H. Matheson (vice-president of Canadian Electro-Products, Ltd., and of Shawinigan Laboratories, Ltd.); hon. treasurer, Mr. T. W. Horner; hon. sec., Mr. J. M. Dickson. The ballot for the election of ordinary members of the committee resulted in the appointment of Messrs. J. B. Bell, R. M. Maclean, G. D. McIntyre, H. J. Roast, and W. B. Woodland; the retiring chairman, Mr. G. R. Hazen, also becomes a member of committee.

BRISTOL AND SOUTH WALES.

The report of the hon. secretary states that the membership of the Section is now about 225. Six meetings were held in Bristol, the average attendance being 40, five in Cardiff and one in Swansea. Mr. C. J. Waterfall was elected chairman, in succession to Mr. Walls, and Mr. A. Marsden succeeds Dr. F. W. Rixon as hon. secretary.

MEETINGS OF OTHER SOCIETIES.

THE FARADAY SOCIETY.

The soil is such a complex mixture of inorganic and organic materials, and is the seat of so many and varied processes—physical, chemical and biological—that the phenomena exhibited by it require for their investigation the co-operation of the physicist, the chemist and the biologist as well as the active support of the agriculturist. It was therefore a very happy idea of the Council of the Faraday Society to organise a general discussion on "Physico-chemical Problems relating to the Soil" and to invite the presence of members of the Agricultural Education Association, the Ecological Society, the Association of Economic Biologists, and other allied societies. The discussion was held on May 31 at Burlington House, with Sir Daniel Hall in the chair. No less than six of the papers communicated were by past or present members of the Rothamsted staff. The discussion was not, however, confined to British workers; two papers were sent by prominent American investigators, and a special feature of the meeting was the presence and active participation of Prof. Sven Odén, of the College of Technology, Stockholm.

Sir Daniel Hall, in his opening remarks, referred to the big change which had taken place in the viewpoint of soil investigation through the modern development of the colloidal hypothesis.

The discussion was opened by Dr. E. J. Russell, who gave, in a general introduction, an explanation of modern views on the constitution of the soil. The mineral particles that make up the framework of the soil are regarded as being coated with a jelly-like colloidal layer of both inorganic and organic material, which has a far-reaching effect on the properties of the soil. The inorganic colloid contained in the clay fraction and the organic colloid both have a large share in contributing to these effects, whilst the effect of calcium carbonate on the state of the clay also has an important influence on soil texture. The soil solution was next dealt with, stress being laid on the disparity between the plant's needs for water and for nutrient salts, so that the very low concentration of the soil solution (*e.g.*, about 0·002% for nitrates) does not necessarily connote any shortage of nutrient material for the growing plant. The absorptive power of the soil colloids and its influence on the composition of the soil solution and on other special phenomeona such as soil "acidity," pan formation, were also considered.

The subsequent papers were divided into four groups. The first of these, dealing with the soil moisture, was opened by Mr. B. A. Keen, of Rothamsted, with a paper on "The System: Soil—Soil Moisture." Work on this subject was critically reviewed, and the various divisions into which soil moisture have been classified were discussed in the light of modern views on the constitution of the soil. The *rôle* of soil colloids in bringing about a progressive gradation in the states of soil moisture, in contrast to the clear-cut divisions formerly imagined, was explained, the various coefficients such as "moisture coefficient," "wilting coefficient," being regarded as equilibrium points between the different states. Recent American work on the osmotic concentration of the soil solution was considered in this connexion. Prof. Odén then read a short "Note on the Hygroscopicity of Clay and the Quantity of Water adsorbed per Unit-Surface," dealing with an interesting application of his new method of mechanical analysis to the determination of the amount of water adsorbed by clay per unit-surface. This application brings out differences due to chemical nature and degree of dispersion, whereas the older Mitscherlich method of calculating the surface of the particles from the hygroscopicity took no account of such differences. Two other papers were communicated in this group, by Prof. D. R. Hoagland, of the University of California, on "The Soil Solution in Relation to the Plant," and by Dr. C. A. Shull, of the University of Kentucky, on "Osmotic Phenomena." In the absence of the authors, *résumés* of their papers were read. The first paper dealt with modern work on the reaction and composition of the soil solution, as they affect, and are affected by, the plant. The second paper discussed the osmotic phenomena concerned in the passage of water from the soil into and through the plant. The nature of semi-permeability in general and of plant membranes in particular was considered; Free's theory of protoplasmic permeability and Loeb's suggestion of electric endosmose were specially noted.

The second group of papers dealt with the organic constituents of the soil. The first paper was by Mr. H. J. Page, of Rothamsted, on "The Part played by Organic Matter in the Soil System." After a critical review of the present state of knowledge of the nature and properties of the humic material in the soil, with special reference to humic acid and to colloidal phenomena, the effect of the humic matter on the properties of the soil was considered under the headings of soil texture, soil moisture, soil temperature, and reaction and composition of the soil solution, and it was shown how the known beneficial effects of organic matter on soil fertility can be largely explained in terms of the colloidal properties of the humic matter in the soil. Prof. Odén then read a paper on "The Application of Physico-chemical Methods to the Study of Humus," dealing specially with his own work on the truly acid nature of humic acid, after which Dr. E. J. Salisbury, of University College, London, brought forward the ecological side of the question in a paper entitled "The Vertical Distribution of Soil Acidity in Natural Soils, and its Relation to Organic Constituents." The different factors influencing the variation of hydrogen-ion concentration with depth in natural soils were considered, with special reference to Cornish woodland soils, and in relation to the degree of humification at different depths; the bearing of these results on the distribution of deep- and shallow-rooted plants was discussed.

The third group of papers dealt with adsorption phenomena. Mr. E. A. Fisher, of the University of Leeds, contributed a paper on "The Phenomena of Absorption in Soils: A Critical Discussion of the Hypotheses put forward." The author made a powerful plea for the more general recognition of the fact that the applicability of an empirical equation such as that of Freundlich to a soil reaction is no criterion of the occurrence of a true adsorption, since such an equation also applies to many reactions which are not adsorptions, and he advanced arguments to show that many of the facts of adsorption by soil are described equally well, and explained more satisfactorily by purely chemical theories developed from that originally advanced by Way. Mr. E. M. Crowther, of Rothamsted, followed with a paper on "Soil Acidity in its Physico-chemical Aspects," in which he dealt with the methods of measuring the so-called "lime-requirement" and the hydrogen-ion concentration of soils; the action of neutral salts on acid soils and the relation of soil acidity to plant growth were further considered. Owing to shortage of time, Mr. C. G. T. Morison did not read his paper on "Pan Formation."

The final group of papers dealt with colloidal phenomena. Prof. Odén opened with a paper on "Clays as Disperse Systems," describing his new method of mechanical analysis and its application

to the examination of certain Swedish clay deposits. Mr. N. M. Comber, of the University of Leeds, followed with a paper on "The Mechanism of Flocculation of Soils," in which he attributed the abnormal flocculation phenomena exhibited by clay in the presence of alkalis to the conferring on the clay of "emulsoid" properties by a coating of colloidal silicic acid around the clay particles, thus affording a satisfactory explanation of what has hitherto been a puzzling anomaly in the behaviour of clay compared with the other soil fractions. Mr. J. W. Robinson, of the University College of N. Wales, Bangor, then read a paper on "The Physical Properties of the Soil in relation to Survey Work," in which he pointed out the need for simple reliable methods of measuring the physical properties of soils as a means of defining their inherent capabilities, since the ordinary methods of mechanical analysis are often useless except for purposes of genetic classification. Dr. J. W. Mellor's paper on "The Plasticity of Clay" was taken as read in the absence of the author.

Although the time consumed by authors in presenting their papers was, perhaps, unduly long in comparison with the time available for discussion, the Faraday Society is, nevertheless, to be heartily congratulated on the success of the meeting.

On June 1 a delightful day was spent at Rothamsted, where Dr. Russell and his staff spared no trouble to acquaint the visitors with the numerous investigations that are being carried out. The morning was spent in the laboratories and the afternoon in the fields. Of great interest were the experimental plots put down to wheat and barley to test the relative fertilising efficiency of sulphate and chloride of ammonia.

SOCIETY OF GLASS TECHNOLOGY.

The May meeting of the Society was held in the University, Sheffield, on May 18, the president, Dr. M. W. Travers, in the chair. The first paper was entitled "The Shrinkage, Porosity and Density of British Fireclays after Firing at 1500° C.," by Edith M. Firth and W. E. S. Turner. Prof. Turner explained that the paper represented a continuation of the work on certain physical properties of British clays which had been described a year ago at Sheffield. The results now presented related to the shrinkage, porosity, and density of the same set of clays between 1400° and 1500° C. In this temperature-range, eight of the clays showed a negative shrinkage (expansion), and two only exhibited a distinct increase in porosity, the rest showing either a small increase or a large diminution. Increased porosity was undesirable, as it was usually a sign of blistering, due to "over-firing." Of the seven clays which showed blistering, five showed the phenomenon only on the surface. Thus 25 out of the 27 clays investigated were usable at 1400°—1500° C., although those which expanded at this temperature would preferably be avoided.

The second paper was by Mr. J. R. Clarke on "The Effect of the Rays of Radium, X-rays, and Ultra-violet Rays on Glass." Seven lime-soda glasses, three of which contained selenium and three cobalt, were exposed to the action of the $\alpha+\beta+\gamma$ rays, $\beta+\gamma$ rays, γ rays, X-rays and ultra-violet rays. The first six were coloured brown by the β rays; the intensity of coloration was greatest on the surface and increased with increasing selenium and cobalt content. As the radiation was prolonged, the intensity increased to a maximum, depending on the percentage of colouring agent, and then remained constant. The seventh glass—pure lime-soda—was only affected by the α rays. None of the glasses was coloured by γ rays, X-rays, or ultra-violet rays with the exposures given. All the glasses fluoresced when kept in radium emanation, but a "fatigue" effect was observed at about the same time as the maximum intensity of coloration was reached. It is thought that the α rays are the chief agents in producing fluorescence, though the β rays are also effective. The colouring is concluded to be due to the formation of colloidal particles in the glasses, and it is suggested that the presence of such particles may be explained by the action of the α or β rays on dissociated ions already present in the glasses.

SOCIETY OF PUBLIC ANALYSTS.

Five papers were read at the meeting held in the Chemical Society's Rooms on June 1, Mr. A. Smetham presiding. In the first paper, on "The Composition of Egg Powder," Messrs. F. F. Beach, T. E. Needs, and E. Russell recorded the results of examining so-called egg powders, comparing them with ordinary baking powders. A table of compositions was given, and it was suggested that a standard based on certain specified figures might be laid down for a minimum percentage of actual egg in such preparations. Mr. N. Evers described the colorimetric method of determining hydrogen-ion concentration by means of indicators, and gave examples of its utility in replacing titration methods in the determination of the "acidity" or "alkalinity" of various products, and of the purity of certain fine chemicals. Mr. F. R. Dodd, in a paper on "The Estimation of Woody Fibre in Cattle Foods," referred to the discrepancies between the results obtained by different analysts working on the same sample by varying processes and suggested a modification of the method to obviate them. The identification of certain fixed oils by the spectrometer was dealt with by Mr. H. C. T. Gardner, who exhibited absorption spectra of a number of vegetable oils and discussed the possibility of identifying such oils by means of absorption spectra. Spectroscopic examination is not sufficient for identification, but evidence of identity can be obtained in certain cases by measuring the positions of the termination of visibility and the extent of visibility of absorption spectra. In the final paper, Mr. J. L. Lizius described the joint use of two indicators in the titration of acids and bases.

THE PHYSICAL SOCIETY.

At the meeting held on May 27, Dr. N. R. Campbell read a paper on "A Method of Micro-analysis of Gases, by the Use of the Pirani Gauge." A well-known equation of the form $\log p = A - \frac{B}{T-T_0}$ expresses the relation between the vapour pressure p of any substance and the temperature T. It can be readily deduced that the value of $\frac{1}{p}\frac{d}{dt}$ becomes infinite as the vapour pressure approaches zero at the temperature T_0, a temperature characteristic of the vapour and called the condensation temperature. If, then, a vapour-pressure-temperature curve be determined for a mixture of condensable gases or vapours, abrupt changes of inclination of this curve are found to occur at temperatures corresponding to the respective condensation temperatures of the constituents of the mixture. These temperatures determine the constituents qualitatively, and the magnitudes of the several abrupt increments of pressure serve to determine the composition of the mixture quantitatively. Mixtures containing minute traces of various gases can be analysed by the method, and to this end a suitable type of pressure gauge has been designed by Pirani consisting of a fine, heated wire immersed in the gas at very low pressure—

of the order of 0·01 mm. of mercury. This wire forms one arm of a Wheatstone network, and the three remaining arms are constituted of manganin resistances. It is found that the electrical energy necessary to maintain the heated wire at a definite excess temperature above its surroundings is a function of the pressure of the gas surrounding the wire. The procedure is therefore as follows: the gauge is connected with a side-tube and the gas therein cooled by immersing this tube in various cooling media, most readily obtained by freezing various substances with liquid air. Thus in analysing a mixture containing phosphorus vapour, water, an unidentified vapour from "vacuum" oil, carbon dioxide, hydrogen, and carbon monoxide, the cooling agents employed are freezing mercury (−39° C.), freezing acetone (−95° C.), freezing ethyl alcohol (−117° C.), liquid air (−183° C.). The side-tube is immersed in each of these baths in turn and the gas pressure determined as above. The various constituents of the mixture are thus readily ascertained both qualitatively and quantitatively. The method is capable of wide application, and it may be applied to the quantitative determination of the several higher unsaturated hydrocarbons present in coal gas.

A paper on "The Intensity of X-ray Reflection by Diamond" was read by Sir W. H. Bragg.

ROYAL SOCIETY OF ARTS.

On May 30 Sir Kenneth Goadby read a paper on "Immunity and Industrial Disease," the Rt. Hon. J. R. Clynes presiding.

The author classified industrial disease under two main types:—(*a*) Primary, due to a specific material handled in the occupation, and (*b*) secondary, non-specific to industry but to which the occupation may predispose. Although the determining factors of most occupational diseases are known, the factor of individual immunity and susceptibility has been neglected. The primary industrial diseases in which immunity and susceptibility play an important part are those due to bacterial infections, diseases caused by actual contact of the hands or body with poisonous material (*e.g.*, TNT, atropine, mercury), and diseases due to dust, fumes, and vapours (*e.g.*, lead, arsenic, paint, dope, etc.). Of the secondary diseases it may be said that they seldom arise from the same causes as those which produce the primary diseases (*e.g.*, tuberculosis among potters is not a consequence of lead poisoning, but of the inhalation of dust particles). Dust, fumes and vapour are responsible for a large proportion of industrial diseases, and individual susceptibility is undoubtedly a significant factor in lead poisoning. The ordinary routine medical examination is of no value for detecting susceptibility owing to the gradual tolerance which is developed by the majority of persons exposed to lead absorption, and which usually occurs within the first three months of exposure. The high incidence of poisoning in the painting trades as compared with white-lead manufacture is difficult to understand, but in many cases it is due to turpentine. The fact that arteriosclerosis (premature degeneration of the blood vessels) with an increase of blood pressure is far more common among painters than among white-lead workers is due to the vehicle in which the paint is used, *i.e.*, mainly to turpentine and its substitutes.

Modern research has shown that the white blood cells are the chief destroyers of living germs and poisons, and that diminished resistance to poisons is accompanied by a decrease in their number. In his researches on the composition of the blood in industrial and other diseases, the author has found that in all chronic infections an alteration in the proportion of white cells may be detected (mainly a decrease in the chief phagocytes), which usually occurs before the outward signs of ill-health are apparent; and that diminution in white blood cells is accompanied by diminished resistance to such poisons as lead, mercury and paint; such persons are particularly susceptible to lead poisoning, etc. He therefore recommends that blood tests (blood pressure and blood counts) be made on persons entering such occupations, so that by eliminating the unfit the incidence of industrial poisoning would be reduced, and some occupations now regarded as dangerous might even be rendered safe. In the painting trade two examinations, one after three and one after six months' employment, would suffice to eliminate susceptible workers. In concluding, the author urged that trade unions should initiate special health committees, not for providing medicine for the sick, but for conserving their capital—health; and in this he was heartily supported by the chairman.

THE CERAMIC SOCIETY.

The Refractory Materials Section of the Ceramic Society held a meeting in Paris on May 11, conjointly with the corresponding French society. Four papers were communicated, the first being a report of "Resistance Tests on Refractory Products under Load at Different Temperatures," by Capt. V. Bodin. The author has experimented with a Frémont machine modified for testing metals, using a special spiral-flame furnace, and a recording apparatus fitted to the machine. The curves thus obtained enabled the crushing load to be determined. The deductions drawn by the author are:—(1) Most refractory products, especially those composed essentially of silica and alumina or silica alone, tend to show a decreased resistance to load on heating, the minimum being generally about 800° C. (2) The same products when further heated show rapidly increasing resistance, with a maximum usually at about 1000° C. For certain clays this maximum may be four times the minimum, or even more. (3) Still further rise in temperature causes a gradual diminution in the resistance, tending towards zero at about 1600° C. with all refractory products. (4) In general, all refractory products tend to become plastic or semi-plastic at about 1200° C. or higher. The minimum is very important practically, as the whole of the refractory masonry of a furnace passes through the critical range of temperature corresponding to minimum resistance, both during the heating and the cooling; trouble may then arise which has hitherto not been explicable.

It is suggested that, though the fusing temperature of a refractory brick cannot be varied by modifying size of grog, compactness, etc., the minimum resistance may probably be raised by this means and the quality of the brick thus improved. The author concludes that the refractory properties of bauxite are improved by raising the firing temperature, as Le Chatelier found with clay. The maximum has not the same practical importance as the minimum, but if refractory materials could be chosen so that their working temperatures were exactly those of maximum resistances (which are not the same for all products), the working conditions would be very favourable to durability.

The second paper was a preliminary note on "Dinas Bricks of Constant Volume," by Prof. O. Rebuffat. The author found that the specific gravity of Lagonegro quartzite is reduced from 2·65 to 2·25 after calcining for eight hours at about 1300—1350° C. He also found that this quartzite contains 0·31 per cent. phosphoric anhydride. On removing the phosphoric anhydride with concentrated nitric acid and calcining the purified rock

for eight hours at 1300—1350° C., the sp. gr. was found to be 2·6. The author also impregnated a very pure primary quartzite of sp. gr. 2·60 (unchanged even after heating for eight hours at 1300—1350° C.) with 3 per cent. of an alkali-glass containing 16 per cent. phosphoric anhydride, and heated the mixture for eight hours at 1300—1350° C. The product had a sp. gr. of 2·27—2·30, and closely resembled the fired Lagonegro quartzite. Having regard to the wide distribution of phosphoric acid in rocks, the author suggests that quartzites which give bricks of constant volume owe their special properties to the presence of small proportions of phosphoric acid.

The next paper was on "Some Difficulties Experienced in Maintaining a Pyrometer Installation in a Works," by Mr. R. S. Whipple. The author attributes want of success in any pyrometer installation nearly always to (1) the choice of the wrong type of instrument, (2) inefficient use of the instrument, or (3) the instrument itself requiring adjustment or correction. Each of these causes was discussed at length.

The last paper, "Notes on American Practice in Refractories," by Mr. W. J. Rees, was the outcome of the author's visit to the United States last autumn. Mr. Rees observed that the outstanding feature of American practice is the well-developed organisation of plant for production at minimum cost. The elimination of hand-labour is a marked feature of the larger plants, and the use of waste heat in tunnel dryers is also noteworthy. Reference was made to a new machine in which, without the application of pressure, the normal operations of the hand-making process are translated into mechanical operations; the machine is tended by unskilled labourers, and the silica bricks produced from it are equal to the best hand-made bricks. The "Dando" ladle brick, which is used to line large basic-steel ladles, lasts 20 to 30 heats, as compared with 8 to 10 heats for high-grade firebricks. The refractoriness of the raw clays varies between cones 16 and 20, and the maximum firing temperature of the bricks is about cone 4. These bricks are made by a dry-pressing process, and the kilns are down-draught, but with eight short chimneys—one between each two fireholes. There is no preliminary drying of the bricks, so the smoking period lasts about nine days and the burning proper a further six days. The manufacture of silica bricks, etc., was described in detail, and developments connected with magnesite and dolomite refractories were discussed.

THE CHEMICAL SOCIETY.

At the ordinary scientific meeting held on June 2, Dr. M. O. Forster presiding, Dr. Harold King, of the National Institute for Medical Research, gave an account of "Derivatives of Sulphur in Commercial Salvarsan." The chief points of interest were that the main sulphur-containing impurity which separates when salvarsan is dissolved in methyl alcohol is a mixed arseno-derivative which on oxidation gives 3-amino-4-hydroxy-5-sulphophenylarsinic acid and 3 amino-4-hydroxyphenylarsinic acid, and that at an intermediate stage in the manufacture of salvarsan the generator of this substance can be isolated in the form of what is probably the corresponding sulphinic acid. Therapeutic experiments on experimental trypanosomiasis in mice point to the undesirability of the presence of this sulphur derivative in commercial salvarsan.

Summarising a paper on "Physical Chemistry of the Oxides of Lead. Pt. I.: The Solubility of Lead Monoxide," Mr. S. Glasstone described the preparation of red-brown, yellow, and red forms of lead monoxide by the action of caustic alkalis on lead acetate solution. The red form probably consists of finely-divided particles of the red, and the yellow form of agglomerated particles of the red. Determinations of the equilibrium solubility and other data indicated that the differences between these three forms of lead monoxide are due to state of division or agglomeration, and not to enantiotropic changes.

A paper on "Latent Heats of Fusion. Pt. I.: Benzophenone, Phenol, and Sulphur," by K. Stratton and Prof. J. R. Partington, was presented by the latter. A weighed amount of the substance is fused by an electric current passed through a heating coil, the material being surrounded by a bath of partly-fused substance at the melting-point. The following values were found, in gram-calories per gram of substance:—Benzophenone 21·7; sulphur (monoclinic) 8·84; phenol 29·06.

Other papers presented in abstract were:—"Researches on Residual Affinity and Co-ordination. Pt. V. Gallium Acetylacetone and its Analogues": G. T. Morgan and H. D. K. Drew. "Some New Tricyclic Bases": T. S. Moore and I. Doubleday. Prof. K. G. Naik summarised his recent work on dithioketones and dithioethers, and Messrs. C. K. Ingold and W. J. Powell their studies of some abnormal condensations of malonic and cyanoacetic esters with halogenated methanes.

PERSONALIA.

Prof. Lemoine, of the Ecole Polytechnique at Paris, has been elected president of the Académie des Sciences.

Dr. William Wilson has been appointed to the London University chair of physics, tenable at Bedford College.

Dr. G. Rutter, deputy-director of research at the Royal Arsenal, Woolwich, has been appointed director of research in succession to Sir Robert Robertson.

Mr. H. Talbot, hon. secretary of the Chemical Engineering Group of the Society of Chemical Industry, has been appointed general manager of the Welsbach Light Co., Ltd.

Mr. K. C. Browning has been appointed professor of chemistry and metallurgy at the Artillery College (formerly the Royal Ordnance College), Woolwich. Prof. Browning was for fifteen years Government Analyst in Ceylon.

On May 9, at Washington, U.S.A., Dr. F. B. Power was presented with a gold medal, conferred by Mr. Henry S. Wellcome, in recognition of his distinguished services to science during the 18½ years he served as director of the Wellcome Chemical Research Laboratories in London. This honour to Dr. Power will be appreciated by his many friends in this country and not least by members of this Society, to whom his work on the Council, the Publications Committee, and the Committee of the London Section is well known.

To the Advisory Committee of the Board of Trade for the Metalliferous Mining Industry, the Secretary for Mines has appointed:—Prof. H. Louis, Dr. J. M. Maclaren, and Mr. T. C. F. Hall (economic geologists); Mr. F. W. Harbord (metallurgist); Mr. T. Falcon, Dr. F. H. Hatch, and Mr. F. Merricks (mining engineers). Sir C. L. Budd is chairman of the Committee, there are twelve representatives of owners of and workers in the iron, tin, lead and zinc-ore mines. Mr. J. J. Burton represents the iron and steel industry, and Sir K. W. Goadby, medical science.

CORRESPONDENCE.

AMERICAN METHODS OF BACTERIOLOGICAL WATER CONTROL.

Sir,—I wish to direct attention to some of the criticisms contained in the review of Milton Stein's "Water Purification Plants and their Operation," by Mr. D. B. Byles in the issue of April 30.

The bacteriological tests, which are stated to be somewhat crude, are, in principle, those adopted by the American Society of Bacteriologists, the American Public Health Association, the American Chemical Society, and the American Waterworks Association. The methods in general are particularly suitable for the control of water-purification plants which, in America, are controlled from works laboratories which are almost invariably staffed by trained men. Whilst the amount of work done on each sample will not compare with that done by the well-known organisation of which Mr. Byles is a member, it must be remembered that the smaller works cannot afford it and they prefer to make five presumptive tests for *B. coli* rather than one test carried to the confirmatory stage. Almost every city with a population of 100,000 and over has its own waterworks laboratory and the scientific control of the purification processes is usually far superior to that in English works, with the exception of the Metropolitan Water Board.

The comparison between English and American standards is entirely misleading, for it is quite erroneous to presume that the latter is a relative one. The American standards are absolute, fixed by the experts attached to the Treasury, and specify that the sample shall not contain more than a definite number of *B. coli* per 100 c.c. The standard, unlike our own, has a definite legal standing.—I am, Sir, etc.,

JOSEPH RACE.

Hereford.
May 18, 1921.

Sir,—In reply to Mr. Race's letter, I would point out that the important test of bacteriological purity of a water is its intestinal-microbic content, and that my criticism was directed to two points, namely (i) that the tests themselves were inconclusive in that the media employed (lactose-broth and litmus-lactose-agar) would include many microbes of non-intestinal origin, and (ii) that the quantity of filtered water tested, namely 0·1, 1, and 10 c.c. in the fluid medium and three 1 c.c. plates in the litmus-lactose-agar, does not permit of very great accuracy; in fact, on these tests it would be impossible to deduce "a definite number of *B. coli* per 100 c.c.," which Mr. Race says is the American legal standard unless that number were 10 or more.

With regard to "standards," I am afraid I used the term somewhat loosely and should have said "the method of expressing results." Several recent American publications which have come to my notice have expressed results in the manner indicated in my review, and this was in my mind when I wrote the words Mr. Race refers to.

I am in full agreement with Mr. Race that, on the whole, the scientific control of American water-undertakings is superior to our own, but it must not be forgotten that, with few exceptions, the supplies to our large towns are derived from upland gathering grounds far removed from any source of pollution.

As I stated in my review, much of Mr. Stein's book is excellent, and presumably the author himself would welcome a reasonable amount of well-meant criticism.—I am, Sir, etc.,

D. B. BYLES.

Metropolitan Water Board, London.
May 24, 1921.

POST-GRADUATE TRAINING IN INDUSTRIAL CHEMISTRY.

Sir,—Mr. Francis H. Carr's paper on the above subject (*cf.* J., 1921, 161 R) comes most opportunely at a time when opinion on this vital question has become dulled by natural relief at relaxation from intensive war effort, by lapse of time from the war period, by the knowledge that money will be required to institute schools such as are outlined, and finally by the serious state of unrest latterly manifested in industry. The need of post-graduate training for those destined to take up the practice of industrial chemistry has been emphasised repeatedly by leaders in science and industry, and if the public could only be brought to realise its importance, the Government might be stirred to action. Now is the time to start this training; to-morrow will be too late.

During the war the Government called on the Universities and Technical Colleges for assistance in the direction and control of scientific warfare in all its phases, and it is well known how well that call was met. The Universities and Technical Colleges now call for aid in founding schools which shall be one safeguard against future unpreparedness. Mr. Carr rightly calls for assistance from the Government, but there is great danger that the swing of the "economy pendulum" will hold back the necessary assistance. Immediate steps, however, could be taken by the Government, without any expenditure of money, and the writer wishes to draw attention to the means available in the hope that some concerted action on the part of those concerned may lead to something being done.

During the war the Government built many national chemical factories for the manufacture of explosives. These were exceedingly well equipped and large stocks of spares were accumulated as necessary to the work in hand. Instead of allowing machinery, plant and stores to lie idle at factories, and I refer particularly to material deliberately acknowledged as surplus Government stock or already advertised for sale, the Government might reasonably place at the disposal of those institutions which have already taken up, or are prepared to take up, training in industrial chemistry such plant and stores as are available. For laboratory equipment there are balances, sample crushers and grinders, electric motors, microscopes, and all kinds of general analytical appliances which would be useful. For technical-scale work there are chemical lead sheeting and piping and all appliances for handling and working same, regulus metal in the form of flanges and valves, lead coils; cast-iron and steel tanks of many varieties and sizes, cast-iron and steel piping, coils and flanges; nuts and bolts, pulley wheels, shafting, belting, agitating gear, steel plates, steel drums, cast-iron and steel valves for all purposes, chemical stoneware tanks, pipes and taps of all varieties, carboys, weighing machines small and large, pyrometers, thermo-couples, indicators and recorders, gauges, acid-ware bricks and tiles, CO_2- and SO_2-recorders, Orsat apparatus sets, centrifugal pumps of cast iron, steel and regulus metal, positive-action rotary pumps, electric motors, tools of every variety, fans and blowers, steel stairways, wood stairways, trucks, trolleys, bucket elevators, band conveyers, portable forges, welding sets, steam boilers, aluminimum ware, and enamelled iron ware.

Naturally, if some of this material were thus made available gratis to the Universities and Technical Colleges the prospective money value would be lost to the Government, and estimates of a possible credit from surplus stores, etc., would have to be adjusted to the extent of a few thousand pounds. However, such credit estimates are only of transient value and it would be well worth while

for the country to exchange some of them, at least, for the solid value which the surplus material would acquire when put to such training purposes as outlined by Mr. Carr. Further, the Government has on hand many surplus buildings of wood, uralite, and corrugated iron. Could not some of these be offered as temporary buildings for those institutions which are not already provided with accommodation for technical chemical work?—I am, Sir, etc.,

Edinburgh University. A. COTTRELL.
May 25, 1921.

NEWS AND NOTES.

CANADA.

Projected Petroleum Refinery at Fort Norman.—It is reported that a small refinery is to be built near the Fort Norman oilfields on the Mackenzie River, British Columbia (*cf.* J., 1920, 435 R), and that the material for the plant has already arrived. It is intended to produce petrol for the local aeroplane and river-transport services.—(*Oil, Paint and Drug Rep., May* 16, 1921.)

JAPAN.

Reported Discovery of a Phosphate Deposit.—According to the *Japan Times*, the "Rasa Phosphate Ore Co.," of Tokyo, has discovered a phosphate deposit on a hitherto unknown island lying to the south of Rasa Island which is superficially estimated to contain 15 million tons. Development work has already begun and the company is negotiating with the banks for a loan of 7 million yen (about £700,000) to finance operations.—(*Chem. Ind., May* 23, 1921.)

AUSTRALIA.

Osmiridium Production in Tasmania.—Practically the whole of the Australian production of osmiridium is derived from Tasmania, where the output in 1920 amounted to 2000 oz., valued at £77,114, the average price being £38 per ounce. At present there is very little market for the product and the Tasmanian Government is investigating the situation. For some years back large quantities of Tasmanian osmiridium have been used in the natural state in the manufacture of the nibs of fountain pens.—(*Bull. Dept. Tr. and Co., Can., May* 16, 1921.)

SOUTH AFRICA.

Industrial Notes.—Recent mining developments include the exploitation on a large scale of the asbestos deposits in the Kuruman and Barkly West districts by a new company with a capital of £150,000, and the working of certain nickel and talc deposits in the Barberton district (*cf.* J., 1920, 271 R, 304 R) by the South African Nickel and Talc Mines, Ltd. (capital £100,000).

Among other industrial developments are the establishment of oil mills at Congella, Durban, by the African Oil Mills, Ltd., and the exploitation of certain fibres in the Cape Province for the manufacture of paper pulp and of jute substitutes by a Johannesburg syndicate.—(*S. Afr. J. Ind., Mar. Apr., May*, 1921.)

Sugar Production in Natal.—It is estimated that the sugar produced in Natal during the 1920–21 season will not exceed 150,000 tons of manufactured sugar, as compared with 185,000 t. in the preceding season. But for the severe drought with which the season opened and the excessively wet period at its close, the yield would probably have been higher by about 50,000 t.; at Illovo, from 12 to 13 t. of cane was required to make a ton of sugar. The production of sugar in Natal during recent years has been as follows:—1916–17, 114,580 t.; 1917–18, 107,000 t.; 1918–19, 155,000 t.; 1919–20, 185,000 t. Formerly sugar-cane was usually planted on large holdings by the owner of a mill, but the present practice is for small holders to plant the cane and sell it to the mills.—(*U.S. Com. Rep., Apr.* 14, 1921.)

BRITISH INDIA.

The Sesamum Industry.—The final estimate of the sesamum crop for 1920–21 is 368,000 tons over 4,291,000 acres, compared with 449,000 t. and 4,254,000 acres in 1919–20. In addition, sesamum is grown in certain other districts, mainly in Burma, the acreage of which has averaged 1,214,000 and the crop 104,000 t. during the last five years. (*Cf.* J., 1921, 87 R.) Exports to countries overseas have been as follows:—1916–17, 84,181 tons; 1917–18, 16,193 t.; 1918–19, 2384 t.; 1919–20, 49,325 t.; and 1920–21, 11,832 t.—(*Ind. Tr. J., Apr.* 22, 1921.)

Exports of Minerals and Metals in 1920.—The Board of Trade has received the following statistics from the Government of India relating to exports of metals and minerals from India during 1920:—

		Long tons.
Brass, bronze and similar alloys		128·35
Chromite		30,675
Copper		79·05
Ferro-manganese		3,877
Iron, pig		44,368
„ other sorts		1,384
Lead, pig		21,477·75
„ other sorts		12·6
Manganese ore		711,424
Tin		3·3
„ ore		704
Wolfram ore		2,934
Zinc or spelter, all sorts		75
Metals, unenumerated		112·45
Ores		1,096
Mica		3,825·85
Monazite		940
Jade stone		221.8
Coal		1,228,408
Mineral oils, benzine ..	(galls.)	21,240,678
„ other kinds ..	(galls.)	823,214
Salt		827
Gold (uncoined)	(oz.)	909,999
Silver	(oz.)	1,644,315

—(*Board of Trade J., May* 12, 1921.)

UNITED STATES.

Synthetic Resins from Furfural.—Now that cheap methods of making furfural from corn cobs have been perfected, it is probable that synthetic resins will be made from it on a commercial scale. These resins soften between 25° and 100° C., and are insoluble in water but readily soluble in benzene, acetone and alcohol; they impart a glossy surface to materials to which they are applied.

Syrup from Sweet Potatoes.—The Department of Agriculture is erecting a semi-large scale plant for the production of a table syrup from sweet potatoes, which is said to be very satisfactory. Sweet-potato flour has not been a success thus far and new methods for its preparation are under consideration. The boll weevil is responsible for the extension of the cultivation of the sweet potato in localities where cotton is no longer profitable.

Recovery of Waste Products in Beet-sugar Manufacture.—A plant for the recovery of waste products from a beet-sugar factory is to be erected at a cost of $104,000. The amounts of these products to be treated are beet-carrying and wash water 2,000,000 gallons, diffusion-battery and pulp-press water 200,000 galls., lime press-cake containing 50 per cent. water 37 tons, and Steffens' house-wastes 200,000 galls. It is intended to recover potash, to increase the yield of sugar, and to discharge the purified effluent into the river.

Magnesite in 1920.—The total sales, and the approximate production, of crude magnesite in the United States in 1919 amounted to 156,266 short tons. During the early part of the year sales were limited owing to the decreased demand from the steel industry which was expecting the arrival of cheaper European magnesite, but this did not happen and buying was resumed in the summer. A Bill was presented to the House of Representatives in 1919 providing for protective duties on imported magnesite, but this was opposed by manufacturers of refractory products, and the Bill had not been passed by January, 1921. Practically all the magnesite produced by the three companies operating in Washington in 1919 was converted into ferro-magnesite and sold to steel plants or makers of refractories; and most of the output of the 18 producing mines in California was used in the manufacture of oxychloride or Sorel cement (finely-ground calcined magnesite mixed with a solution of magnesium chloride and certain filling materials). The use of magnesite cement for flooring and wall plaster is extending. Imports of magnesite amounted to 15,852 short tons, of which Canada supplied approximately 51, Austria-Hungary 17, Mexico 16, and Italy 16 per cent. (*cf.* J., 1919, 456 R).—(*U.S. Geol. Surv., Mar.* 7, 1921.)

Lithium Minerals in 1919.—According to the United States Geological Survey, the output of lithium minerals in that country was 6287 short tons in 1919, or more than ten times greater than in 1916. South Dakota and California supply practically the entire output and the deposits are ample to supply requirements in the United States for a long time to come, even if unexpected uses should be discovered. The chief lithium minerals are lepidolite, a lithium mica obtained largely from California, spodumene, a lithium-aluminium metasilicate from South Dakota, and amblygonite, a phosphate and fluoride of aluminium and lithium, also from S. Dakota. A lithium mineral is also won in Spain at a single mine in the province of Caceres, which produced only 11 t. in 1918. Much of the lithium minerals produced is manufactured into lithium hydroxide, which is used in a certain type of storage battery, lithium salts and lepidolite are used in glass batches to reduce the viscosity of the glass (U.S.Pat. 1,261,015; J., 1918, 418 A), and the fluorine in the mineral as an opacifying agent for opal glass. Lepidolite might also be used to reduce the viscosity of enamels, but so far as is known it has not been utilised for this purpose. The bromide and iodide have been used in photography and the cyanide in X-ray work; the chloride is used to some extent in pyrotechny; and the carbonate, mixed with carmine, is used as a nuclear stain. Coal-tar products have largely superseded lithium salts in the treatment of rheumatism and allied affections.

Sodium Compounds in the United States in 1920.—The following preliminary figures of production, importation and exportation of sodium compounds in the United States in 1920, compiled by the U.S. Geological Survey, have been supplied by the Department of Overseas Trade (from the *Journal of Commerce, N.Y.*). Sales for the year amounted to 9,886,020 short tons, valued at $139,336,338, which represent an increase of 8 per cent. in quantity and 17 per cent. in value compared with 1919. Considerable decreases took place in the sales of sodium bichromate, ferrocyanide, nitrate, thiosulphate, and sal soda, but there were large increases in sales of bicarbonate, bisulphate, phosphate, borate, and soda ash. Sodium compounds derived from natural sources (excluding common salt) increased to 42,683 t., valued at $1,513,179. Imports of sodium compounds also increased, but only in the case of sodium nitrite did importation exceed production. The exports, chiefly to Japan, Canada, and Mexico, are believed to constitute a record.

Sales of Chief Sodium Compounds, 1919-20.

	Short tons. 1919.		Short tons. 1920.
Sodium acetate	778	..	1,020
Sodium bicarbonate	134,962	..	188,906
Sodium bichromate	26,526	..	25,973
Sodium bisulphite	11,819	..	22,059
Soda ash	981.054	..	1,242,490
Sal soda	80,090	..	62,857
Sodium hydroxide	311,388	..	382,680
Sodium phosphate	14,760	..	30,515
Sodium silicate	300,138	..	304,503
Salt cake	134,685	..	184,946
Glauber's salt	42,087	..	44,479
Nitre cake	83,402	..	308.638
Sodium sulphide	45,448	..	42,952
Sodium tetraborate	28,518	..	35,281

Imports.

	Short tons. 1919.		Short tons. 1920.
Sodium chlorate	262	..	281
Sodium cyanide	1,208	..	3,795
Sodium nitrate	1,024,053	..	1,480,519
Sodium nitrite	4,570	..	4,845

Exports of Domestic Products.

	Short tons. 1919.		Short tons. 1920.
Soda ash	50,481	..	8,338
Sal soda	5,553	..	6,015
Caustic soda	82,118	..	112,069
Sodium silicate	12,150	..	17,048

Better prices for sodium compounds were obtained in 1920 than in 1919, although they fell off towards the end of the year. Sodium sulphate was in great demand from abroad. Prices of the raw materials used in the manufacture of sodium compounds now appear to have come down almost to pre-war levels.

GENERAL.

British Laboratory Ware.—The question of the quality, supply, and prices of British laboratory glassware, porcelain, and chemicals, including research chemicals, is being considered by a committee of the British Science Guild, of which Sir Richard Gregory is chairman. In view of the conflicting statements which have appeared from time to time on these matters, the committee is anxious to obtain the views of scientific workers who have experience of recent articles of the kind described, both of British and foreign manufacture. It is obvious that the information can be of use only when it applies to goods of definitely known origin. The points on which information is desired are:—The quality of the goods; their price as compared with that of imported articles of the same quality; the facilities for obtaining supplies; and the effects, if any, on research work of restrictions imposed on the importation of German goods. The committee would also welcome statements made, or reasoned conclusions arrived at, by competent bodies which have investigated these questions recently, and from manufacturers who wish to add any further definite information to that which has already appeared in the Press. The information should be sent as soon as possible to the secretaries of the committee, Prof. J. R. Partington, East London College, or Mr. C. L. Bryant, 23, Peterborough Road, Harrow.

Carbon Monoxide Poisoning.—With the object of obtaining accurate data concerning the after-effects of inhaling carbon monoxide, and their influence on loss of working time, a systematic survey has been made in eight States of America of cases occurring in metalliferous mines, coalmines, engine-rooms, and in industries using blast furnaces and producer-gas boilers. It was found that carbon monoxide rarely causes late after-effects following acute gassing and that when such effects do appear, there is nearly always evidence of a pre-existing pathological condition. Frequent exposure to carbon monoxide causes headache and malaise, but no evidence of a cumulative harmful effect was obtained;

permanent compound with hæmoglobin. A certain tolerance to the gas can be acquired, owing to the compensatory increase of hæmoglobin and red cells, induced by prolonged want of oxygen. An advance in treatment has been made by adding carbon dioxide to the oxygen inhalations administered, recovery being three times as rapid as when oxygen is used alone. The U.S. Chemical Warfare Service has perfected a portable respirator which is effective even at 0° C. against 1 per cent. of carbon monoxide; its life is approximately three hours.—(*J. Ind. Hygiene, May*, 1921.)

"**Zinc (1913—1919)**," issued in pamphlet form (112 pp., price 3s. 6d. net) by the Imperial Mineral Resources Bureau, consists of a digest of statistical and technical information relative to the production and consumption of zinc in the British Empire and foreign countries. The fact is emphasised that within the Empire are to be found some of the largest deposits of zinc ore in the world, viz., Broken Hill, Australia, Bawdwin Mines of Burma, Rhodesian Broken Hill and British Columbia. Yet, prior to the war, these ample resources of raw material were little utilised by British smelters. In England, ores imported chiefly from Spain, Algeria and Sardinia were mostly used. The only plant treating Broken Hill concentrates was that at Seaton Carew, where the concentrates are roasted and the zinc distilled, sulphuric acid being recovered as a by-product; and the only smelter plant in the Empire, other than in England, was at Port Pirie, Australia.

The usual valuable bibliography is given to cover the period, and an interesting feature of the publication is an appendix occupying seven pages on "The Zinc Industry at the close of 1919," by Mr. Gilbert Rigg of the Broken Hill Associated Smelters. Mr. Rigg, who discussed the subject from both the technical and economic points of view, expresses the opinion that, although many improvements had been effected in the distillation process resulting in increased capacity, fuel economy, and improved recoveries, the electrolytic process, perfected and developed during the war by such companies as the Anaconda Copper Co., U.S.A., and the Trail Consolidated Smelters, Canada, that were previously in no way concerned with zinc production, had come to stay. On the other hand, the electrothermic process can be considered as hardly taking rank with the distillation and electrolytic methods, the successful condensation of the zinc vapour being even more difficult and complicated than in the distillation process.

Industries in Egypt.—Although essentially an agricultural country, Egypt possesses a few manufacturing industries and the Government is doing all it can both to strengthen those already existing and to foster new ones. A Government Bureau of Commerce and Industry has been organised for the promotion of native industries, and the Department of Technical Industry and Commercial Education controls 17 trade schools which are turning out skilled manual workers. Among Egyptian industries, sugar-refining takes first place. This industry is monopolised by a company with a capital of 114 million francs which owns a refinery with an annual capacity of 100,000 tons of sugar. During 1918, 79,488 t. of sugar and 37,330 t. of molasses were produced from 814,842 t. of cane. Alcohol is produced from molasses at a distillery with a capacity of about 2,200,000 gallons per annum. An export trade in alcohol was built up prior to 1917 when exportation was prohibited. Small quantities of such by-products as potassium carbonate, chloride and sulphate, and carbon dioxide are produced, and sugar-straw is manufactured for use as fodder. The cottonseed-crushing industry is of some importance, but only local requirements are supplied; the equipment of the mills is mostly modern and an oil of good quality is produced for edible purposes or for the manufacture of a low-grade soap. Tanning and leather-working are widely practised, pottery is still a flourishing industry, and the manufacture of cement is increasing in importance; bricks and tiles are made at El Widi, south of Helwan, and an impure fireclay is worked at Assuan. Factories for the manufacture of paper, rubber, etc. have been established in recent years, and brewing as well as the distillation of potable spirits is carried on. The most important mineral product is petroleum, the output of which has risen from 12,786 t. in 1913 to 281,885 t. in 1918. Hurghada is the chief producing centre and the oil is refined at Suez in a plant with a daily capacity of 1200 tons. In view of the growing importance of oil fuel, further prospecting work is to be carried out. The mining of phosphate rock is also of growing importance.

Cost of Fixed Nitrogen in Norway.—T. C. Hagemann, consulting engineer to the Norwegian nitrate industry, Christiania, has given the following approximate figures of costs for the arc process of nitrogen fixation in order to show that this process is profitable in Norway.

Assuming a yield of 540 kg. of nitric acid (calculated at 100 per cent. per kw.-yr., or 62·5 g. per kw.-hr.), a medium-sized factory (about 40,000 kw.) in Norway will produce yearly about 20,000 tons of nitric acid, equivalent to 4500 t. of nitrogen, in the form of 29,000 t. of Norwegian saltpetre (13% N) and 4400 t. of sodium nitrate (16·5% N). The approximate running expenses are (krone=1s. 1½d. at par):—

	£
Power, 40,000 kw. at 12s. 6d.	225,000
Administration and wages	84,375
Raw materials, etc.	61,875
Packing	56,250
Sundries	22,500
Total	£450,000

The raw materials required are limestone 15,000 t., lime 500 t., and soda 2500 t. The market price of the nitrogen in the above-mentioned products is about £168 15s. per ton, so that 4,500 t. would sell at £759,375. The profit, therefore, is £309,375, and assuming that the capital invested be about £1,125,000 and amortisation charged at 7½ per cent., the total net profit would be £225,000. As power represents half the running expenses, this item, together with the future yield, is vitally important when considering the cost and returns of any individual factory. Calcium nitrate is now being exported from Norway in increasing amounts. —(*Chem and Met. Eng., March* 23, 1921.)

The Sulphur Industry in Sicily.—The year 1920 was marked by considerable increases in the production and exportation of Sicilian sulphur; production rose from 181,744 to 240,857 metric tons, the exports increased from 147,286 t. to 188,865 t., and stocks at the end of the year were 147,900 t. as against 137,100 t. in 1919. Relatively good as these figures are, they compare badly with those for 1914, when 340,700 t. was exported and stocks mounted to 359,800 t. Exports to France have decreased from 60,700 t. in 1914 to 37,100 t. in 1920, to Austria from 25,300 t. to 700 t., to Germany from 18,800 t. to 4,700 t., to Russia from 21,200 t. to 2,200 t., to Scandinavia from 25,200 t. to 4,800 t., and to England from 12,900 t. to 11,600 t. On the other hand exports to Spain and Portugal have increased from 21,400 t. to 30,700 t., and to South America from 900 t. to 8000 t. Exportation has naturally been affected by the fluctuating exchange, but the increasing competition from Louisiana sulphur will, it is anticipated, bring about a reduction in prices.—(*Chem. Ind., Apr.* 25, 1921.)

Saltpetre Deposit in the Sahara.—The scarcity of saltpetre in France during the war induced the French Government to send out a technical commission in 1917 and 1918 to investigate the saltpetre deposits situated in the Sahara between Sba and Ouled-Mahmud. Disappointing results were obtained by the Commission, the reserve of saltpetre earth being estimated at only 900 tons. About 60 tons of saltpetre was obtained from this source during the war with an average composition of KNO_3 53—55%, $NaNO_3$ 31—33%, NaCl 2—6%, sodium, calcium, and magnesium salts being also present in small amounts. In view of the small value of the deposits the Commission, which continued its investigations until November, 1919, has advised the French Government to discontinue development work. The product differs from Chile saltpetre chiefly in its high but fluctuating content of potassium nitrate.—(*Chem. Ind., Apr.* 25, 1921.)

Electrolytic Sodium Perborate.—According to a recent patent of the Norwegian firm Fredrikstad Elektrokemiske Fabriker, the process for manufacturing perborate by electrolysis has been simplified and rendered more efficient by employing an electrolyte containing, besides borax, a certain amount of sodium cyanide. Hitherto, concentrated solutions of borax and a large amount of sodium carbonate have been considered necessary for success and the presence of certain metallic impurities has diminished the current efficiency. These difficulties, it is claimed, have been surmounted, so that a dilute solution of borax may be employed, and the presence of sodium cyanide in the electrolyte prevents metallic impurities from bringing about the decomposition of the perborate and thus diminishing the yield. The process appears to be a marked improvement on those already introduced for the manufacture of this valuable per-salt.—(*J. of Commerce, N.Y., Apr.* 21, 1921.)

Mexico in 1920.—The Ensenada district of Mexico includes a large part of Lower California where there are large undeveloped deposits of gold, silver, copper and iron. Copper ore is produced at the El Boleo mine near Santa Rosalia, which is owned by French and Dutch interests and is said to have supplied over 100,000 tons of metal since it was started in 1887. At the present time seven reverberatory furnaces and a 150-ton oil furnace are being used. The Alamos gold district, formerly very important, is being re-opened, silver is being mined near La Paz, magnesite near Magdalena Bay, manganese near Mulege, and tungsten at Real del Castillo. Near Santa Catalina there is an onyx quarry said to be the largest deposit of the kind. Petroleum has not been found in Lower California, but indications are said to be favourable and American, British and Mexican interests have acquired concessions. Another product of this district is sea-bird guano, of which 478 tons was exported in 1919 and 234 t. in 1920. The only resources of the Frontera district are agricultural and forest products; in 1920 the production of cacao amounted to 1478 t., the largest crop since 1913, and that of unrefined sugar to 3000 t. The possibilities of sugar production in the State of Tabasco are very great; and two companies are prospecting for oil, which is believed to occur in large quantities. Henequen fibre is the chief industry of the Progreso district and constitutes about 98 per cent. of the total exports. Although 154,248 t. of fibre was exported in 1920, the actual production was about 126,298 t. The Vera Cruz district is essentially agricultural, producing coffee, vanilla, chicle, and hides. Owing to the bad weather the vanilla crop is expected to be only one-half of that of last season's (about 142 t. of beans). The crop of chicle is very poor, and the production of hides has been much reduced by the destruction of livestock during the revolutions.—(*U.S. Com. Rep., Mar.* 23, 1921.)

PARLIAMENTARY NEWS.

HOUSE OF COMMONS.

Paper-making Industry.

In a written answer to Rear-Admiral Adair, Sir P. Lloyd-Greame said that at present many paper mills were either closed down or working short time, owing to the high cost of raw materials, the increasing amount of paper imported, and the decline in demand. In so far as foreign competition was from countries with depreciated currencies, no industries other than food industries would be excluded from the provisions of Financial Resolution No. II., relating to the safeguarding of industries.—(May 24.)

Oil-boring in Great Britain.

Replying to Major Kelly, Sir R. Horne said that of the eight boreholes completed, one was producing oil in commercial quantities and the remaining seven were being closed down; three other borings were still in progress. The date of termination of the agreement with Messrs. S. Pearson and Sons, Ltd., depended largely on the settlement of the question of the ownership of the petroleum discovered, in respect of which legal proceedings were pending. In the meantime, expenditure was being reduced.—(May 24.)

Coal Imports.

Mr. Bridgeman, in answer to Mr. W. Thorne, stated that the import of coal into the United Kingdom in 1920 amounted to 3671 tons, of an average c.i.f. value of 145s. 1d. per ton. During January, February, and April, 1921, the imports were 142 t. (80s. 5d.), 5591 t. (47s. 8d.), and 2818 t. (58s. 2d.), respectively. No coal was imported in March, 1921.—(May 26.)

In reply to Mr. J. Guest, Mr. Bridgman said that since the stoppage of work in the mines 94,000 tons of German reparation coal had been imported into this country. He was not aware that the German Government had protested against the exportation of this coal by France and Belgium.—(June 1.)

Subsidies to Rubber Planters.

In reply to Sir W. de Frece, Mr. Churchill said that he understood that certain foreign Governments granted a subsidy to rubber planters under their jurisdiction. He was not aware that a similar action was contemplated in any British Colonies.—(May 31.)

Home-Grown Sugar, Ltd.

Answering Mr. Wise, Sir A. Boscawen said that the value of the property, including the factory, estate, farm stock, etc., of Home-Grown Sugar, Ltd., was £447,659 on March 31 last. Shares had been issued to between 500 and 600 shareholders to the amount of £500,000, of which £498,415 15s. had been paid up. There were no debentures, but the company was negotiating a first mortgage of £75,000 to be secured on the property (*cf.* J., 1921, 108 R).—(May 31.)

British Dyestuffs Corporation.

Capt. W. Benn asked the President of the Board of Trade whether the British Dyestuffs Corporation had refused to supply British export firms with synthetic indigo on the ground that the Corporation had its own agents in the Far East; and what steps the Government proposed to take in the matter. Sir P. Lloyd-Greame replied to the effect that the arrangements made by the British Dyestuffs Corporation with its agents in China preclude the sale of its products to merchants in this country when the goods are destined for export

to, and sale in, China. Merchants who supply the Chinese market can, however, obtain their supplies through the Corporation's agents in that country without disclosing information as to the ultimate purchasers. The Government is not responsible for the management of the British Dyestuffs Corporation and the Board of Trade has no power to dictate to firms the terms of their agency agreements.—(June 6.)

The Jamaican Citrus Industry.

Mr. Churchill, answering Mr. Hard, said that he had received suggestions from the Governor of Jamaica to the effect that the citrus-fruit industry of the Colony would be benefited if the Canadian Government would grant certain facilities in addition to those provided under the Canada-West Indies Agreement; correspondence was now proceeding with the Dominion Government on the subject.—(June 1.)

Safeguarding of Industries Bill.

During the debate on the financial resolutions, which form the basis of the Bill, Mr. Wise (Ilford) argued in favour of the 33⅓ per cent. import duty on fine chemicals. In his constituency there was a large chemical factory, established in 1797, which was feeling German competition so acutely that it had almost closed down and about three-fourths of its workers was unemployed. Mr. A. M. Samuel said that the world's production of optical glass did not amount to 50 tons, valued at about £50,000 at present, but that amount would suffice for the manufacture of optical instruments worth £30,000,000; the production of this indispensable commodity should not be allowed to pass out of our hands. Criticism was levelled against the quality of the arc-lamp carbons produced in this country, but Sir P. Lloyd-Greame said that they satisfied Admiralty requirements.

The debate on the second reading of the Bill was held on June 7 and 8, and the motion for the second reading was passed by 312 votes to 92.

LEGAL INTELLIGENCE.

Alleged Infringement of German Sulphur-Black Dye Patent. *A.-G. für Anilin Fabrikation in Berlin v. Levinstein, Ltd.*

On May 9 the Court of Appeal, consisting of the Master of the Rolls and Lords Justices Warrington and Younger, dismissed an appeal by the A.-G. für Anilin Fabrikation in Berlin and the liquidator of the Mersey Chemical Works from a judgment given by Mr. Justice Sargant in February, 1914, dismissing the action brought by them against Levinstein, Ltd., for alleged infringement of a patent (1151/1900) for the manufacture of Sulphur Black dyes.

Counsel for appellants said that the patents taken out from 1873 onwards for processes of manufacturing dyes involving reaction between an alkali sulphide, sulphur, and an organic substance culminated in the Cassella patent of 1896, which, however, never came into use in this country. In these processes melting was necessary, and in 1900 appellants patented a process in which, although the reagents employed were the same as those specified in the Cassella patent, the melting was replaced by boiling. According to the appellants' specification, sodium sulphide and dinitrophenol were to be used, but in practice these were replaced by sodium dinitrophenolate. As the respondent company had not used dinitrophenol but its sodium salt, it had been held that there was no infringement. Appellants, however, claimed that the respondents' process was a colourable imitation of theirs and that the two processes were chemically identical.

For the respondent company it was submitted that the Cassella process was not a melting process but a boiling process, and that there was no subject matter for the appellants' patent. If, however, the Judge was right in holding that there was sufficient invention in that patent to give it subject matter, then it followed that the use of the sodium salt in the Levinstein process gave it sufficient distinction from the appellants' process to make it impossible to allege infringement. All arguments to show that there was subject matter applied equally to show that there was no infringement.

In dismissing the appeal Lord Justice Warrington said that the defence of insufficiency of subject matter and insufficiency of description failed. The main issue was that of infringement, and the Court had concluded that the appellants' specification was confined to a process of boiling dinitrophenol. The use by Levinstein, Ltd., of sodium dinitrophenolate was a different process, and the boiling of this salt with the solution mentioned in the appellants' specification would not be covered by their patent unless it could be proved that this process was common knowledge in 1900, the date of the patent. Appellants had not shown this, and their claim for damages for infringement failed.

REPORTS.

Report of the Industrial Alcohol Committee, India, 1920. *Pp.* 62. (*Simla: Superintendent Government Central Press.*)

The Industrial Alcohol Committee was appointed to consider and report on the extent to which the existing excise regulations in India would require amendment in view of the possibility that the large-scale manufacture of industrial alcohol might be undertaken in the near future. The Committee found that the existing regulations, although adequate at present, would need alteration; that restrictions in production would have to be maintained even if those on sales, storage and transport were relaxed; that one possible obstacle to the manufacture of industrial alcohol is the seeming confusion of the rules concerning it; and another the restriction imposed by the Railway Board on the transport of alcohol in tank wagons which should be abolished.

The recommendations of the Committee include the following, among others:—Experiments should be made to determine if alcohol 55° overproof, denatured with 0·5 per cent. caoutchoucine, 1 per cent. pyridine, and a certain proportion of methyl violet, can be safely released from all excise restrictions except those regarding renaturation; and if such experiments prove successful, further tests should be undertaken to ascertain if spirit so denatured could be used advantageously in internal-combustion engines. If these further experiments were also satisfactory, or a better denaturant were discovered, a standard denaturant should be adopted for power alcohol throughout the whole country: such alcohol should be exempted both from excise duty (whether it be made in the country or be imported and then denatured) and from duty under the Motor Spirit Act. Power alcohol should be transported by rail on the same terms as dangerous petroleum; and special licences should be granted for the use of rectified or specially denatured spirit in industries.

An appendix to the report contains, in tabular

form, a list of industries in which alcohol is used, the form of alcohol which might be employed, the suggested place of denaturation, and suggested methods and formulæ for industries requiring specially denatured spirit.

Report on the Commercial, Industrial and Economic Situation of Italy in 1920. *By* Sir E. Capel Cure, *Commercial Counsellor, and* J. H. Henderson, *Commercial Secretary to H.M. Embassy, Rome. Pp.* 48. *Department of Overseas Trade. London: H.M. Stationery Office.* 1921. *Price* 1s.

The war left Italy in a disorganised and exhausted condition, but as natural resources and advantages, except possibly that of cheap labour, are still intact, eventual recovery may be anticipated; the chief obstacles thereto at the present time are labour unrest and depreciated currency. In 1919 industrial materials formed 52·5 per cent. of the imports, foodstuffs 32·2 per cent., and manufactured articles 15·3 per cent., these figures comparing with 57·3, 23·4, and 19·3 per cent., respectively, in 1913. The excess of imports over exports rose from 1134 million lire in 1913 to 11,328 millions in 1919, but there was a notable improvement during the first eight months of 1920. In 1919 the share of the United States in the foreign trade was 50 per cent. of the imports and 9 per cent. of the exports; that of Great Britain was 14 and 13 per cent., respectively. Germany, formerly first, now takes the sixth place with a volume of trade one-sixth that of the United States and one-fourth that of Great Britain. Germany supplies chiefly machinery, iron and steel, dyes and small hardware goods, and appears to be rapidly regaining its former ascendancy. There has been an enormous increase in the capitalisation of joint-stock companies since 1916; this still continues, and will undoubtedly be a grave source of danger when prices and profits decline; the net increases, in millions of lire, of chemical companies were 172·1 in 1918 and 133·2 in 1919, and of metallurgical companies, 725·5 and 214·2, respectively. Concomitantly, the values of industrial securities have seriously depreciated; in the chemical industries the index number fell from 100 in December, 1919, to 78·59 at the end of October, 1920, and that for the iron and steel industry from 102·49 to 51·10.

Agriculture showed a significant improvement in 1920, but as over 90 per cent. of the country is already cultivated, increased production will only be achieved by improved methods of cultivation. The annual production of citrous fruits, of which 52 per cent. is lemons, is about 800,000 metric tons, and that of essences and calcium citrate about one-tenth of the world's output. The sugar-beet, but recently introduced, is now cultivated on a large scale, and the national factories are producing nearly sufficient sugar to meet the home demand. Increased production of fertilisers and development of hydro-electric power are signs of the progress being made; but many years must elapse before the latter can have any marked effect on industrial productivity. A Government commission has been appointed to investigate Italian fuel resources, but it is doubtful if the results will justify the heavy expense, especially for boring, that will have to be incurred. Mineral production is probably much lower than the potential output, and the mineral wealth of the redeemed provinces is unlikely to affect the general position. During 1919 Venezia Tridentina and Venezia Giulia produced:—Copper ore, 26 metric tons; lead ore, 1082 t.; zinc ore, 20,149 t.; iron pyrites, 100 t.; mercury (metal), 297 t.; lignite, 93,300 t.; coal, 870 t.

OFFICIAL TRADE INTELLIGENCE.

(*From the Board of Trade Journal for May* 26 *and June* 2.)

OPENINGS FOR BRITISH TRADE.

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W. 1, from firms, agents or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number:—

Locality of firm or agent	Materials.	Reference number.
British West Indies	Drugs, bottles, chemicals for confectionery and aerated water trades	667
Canada	Vegetable colours for jam and confectionery, dyes for textiles, pigments	641
"	Pigments, dry colours, lithopone, litharge, zinc oxide, china clay	646
"	Medicated confectionery	668
"	Insulating varnish..	671
"	Mining supplies	674
"	Chinaware	675
Egypt	Calcium carbide (tender for) ..	—
Italy	Metals	686
Spain	Tinplate	657
"	Rubber	658
Smyrna	Sugar, paper, chemicals, carbide, petrol, pottery, glass, perfumery	660
South Africa ..	Paper	680
Netherlands East Indies	Chemicals	9744 F.W./P.N.
United States ..	Dry white lead	697
Argentina	Heavy and fine chemicals ..	664

Markets Sought.—A company in eastern Canada about to manufacture milk powder wishes to arrange for sale in the U.K.

[Inquiries to the Canadian Government Trade Commissioner, 73, Basinghall Street, London, E.C. 2.]

TARIFF. CUSTOMS. EXCISE.

Australia.—Recent customs decisions affect glucose, perfumed spirit, candles, matches, and paraffin wax.

Belgium.—The import of malt and the export of malt and matches are now permitted without licences.

British West Africa.—The import duty on spirits has been increased.

Canada.—It is proposed to amend, as from May 10, the import duties on cocoa, chocolate, coconuts, sugar, alcohol, spirits, and perfumes.

Denmark.—The export of potash and potash salts is allowed as from May 3.

Ecuador.—Sugar may now be exported subject to an export tax of 15 per cent, *ad valorem.*

France.—Until further notice the export is permitted of margarine, edible vegetable fats, bauxite, and iron ore.

French West Africa.—The import is prohibited of "trade spirits," thuyone, badian, benzoic aldehyde, salicylic ether, hyssop, and absinthe.

Germany.—Entry permits are required on entry into unoccupied Germany from occupied Germany of cocoa, cocoa husks, chocolate, artificial honey, refined sugar, margarine, compound lard, fertilisers, artificial sweetening matter, rubber tubing and tyres, asbestos wares, etc.

Jamaica.—The export of cocaine, opium, and certain explosives is prohibited to all destinations other than the British Empire.

Latvia.—Special export licences are no longer required for lime, gypsum, pottery, cardboard, cork, china, glassware, matches, soap, syrup, tar, turpentine, varnish, and window-glass.

Mexico.—The import of oleostearin is duty free.

Netherlands.—Export prohibitions have been withdrawn from ferruginous earth containing sulphur, and potassium salts.

New Caledonia (French).—The export duties on raw hides and skins and copra have been abolished, but minerals, whether in the form of ore or matte, pay 3½ per cent. *ad valorem.*

Paraguay.—The export duty on quebracho extract has been reduced to $3 (gold) per metric ton.

Peru.—Vanadium ores with less than 10 per cent. of vanadic acid may be exported duty free.

Spain.—The full text of the new provisional Customs Tariff is issued as a supplement to the issue of May 26. The tariff is to remain in force pending a further revision of a more permanent character and is operative as from May 21.

All classes of goods are affected, and in most cases the duties are increased. Among the articles on which the duties have been reduced are chinaware, perfumery, spirits, and rubber wares. Additional surtaxes are levied on petroleum, coconut oil, palm oil, indigo, manilla hemp, agave, jute, raw hides and skins. Export duties are payable on cork, bones, galena, litharge, lead ores, argentiferous lead, iron ore, copper ore and copper matte. Sheet, plate, and crystal glass when imported coloured, bevelled or engraved pays in respect of each such operation a surtax of 10 per cent. of the duty applicable. Bimetal sheets are classed under the heading of the more highly taxed metal. Tarred or impregnated timber pays the duty applicable plus a surtax of 10 per cent.

Sweden.—Export prohibitions have been withdrawn from mineral and lubricating oils.

It is proposed to increase the import duties on many classes of goods. The schedule of articles affected is set out in the issue of June 2.

United States.—The Emergency Tariff Bill became effective on May 28. For a period of 3 months the admission is prohibited of sodium nitrite, dyes, crudes or intermediates, products derived directly or indirectly from coal tar, and synthetic organic drugs or chemicals, unless a satisfactory substitute therefor is unobtainable in the United States.

GOVERNMENT ORDERS AND NOTICES.

German Reparation (Recovery) Act.—An Order has been issued by the Board of Trade under the above Act exempting from its provisions any article proved not to have been first consigned from Germany to the United Kingdom. Goods are regarded as consigned from the country where they were last owned, and from which they were procured by the importer. The Order No. 5 has been cancelled.

Leather Measurement Regulations, 1921.—In view of the increasing use of leather-measuring instruments in the leather trade, regulations have been made by the Board of Trade under the Weights and Measures (Leather Measurement) Act and will come into force on July 1. After that date every leather-measuring instrument of an approved pattern must, if used for trade, be verified and stamped by an Inspector of Weights and Measures within a period of twelve months.

TRADE NOTES.

BRITISH.

British Guiana in 1919.—Owing to scarcity of labour, bad weather, and shortage of nitrogenous fertilisers, the sugar crop amounted to only 86,971 tons, of which 83,140 t. was exported, mainly to the United Kingdom. The acreage under cacao remained at about 2000 acres, but the planting of Para rubber decreased. Para rubber grows well on suitable lands in the colony and gives good yields, but is susceptible to leaf disease. Balata bleeding was continued and 627·3 t. was exported. Coconuts are now planted over 27,400 acres, an area which could be greatly increased; 4,693,000 nuts, 68 tons of copra, and 9120 galls. of coconut oil were exported. Limes are cultivated over about 1350 acres, and the erection of factories for the production of concentrated juice and citrate of lime has given the industry a much-desired impetus; the exports were 389·5 cwt. citrate of lime, 7356 galls. of raw and 2882 galls. of concentrated lime juice, and 326 galls. of oil of limes. During the year 16,216 oz. gold and 16,706½ carats diamonds were produced, and eight licences were issued for mineral oil exploration in the north-western and Pomeroon districts, but no definite results were recorded. The principal exports include sugar, rum, molasses, molascuit, rice, and citrate of lime. Leather, cacao and matches are manufactured, and there is a larg ice factory. The value of the exports wa £4,240,832, an increase of 20·21 per cent. on 191 and imports were valued at £3,590,812. Th United Kingdom takes first place with 34·13 pe cent. of the total trade of the colony, followed b Canada and the United States with 30·54 and 17· per cent., respectively.—(*Col. Rep.—Ann.*, No. 1068, *Mar.*, 1921.)

FOREIGN.

Imports of Chemicals into the Dutch East Indies.—H.M. Commercial Agent at Batavia, Netherland East Indies, has supplied the Department of Overseas Trade with the following statistics relating t imports of chemicals into the Netherlands East Indies during 1919.

The following statement shows the quantity an value of the various chemicals imported into th Dutch East Indies during 1919:—

	Quantity. Metric tons.	Value. £
Alum	1,620	16,190
Ammonia	33	9,080
Acetic acid	221	31,310
Calcium carbide	767	32,830
Caustic soda	2,869	99,030
Sodium nitrate	84	2,670
Sodium sulphate	1,791	35,440
Copper sulphate	46	2,080
Sulphur	3,293	43,910
Sulphur pyrites	9,160	48,180
Sulphuric acid :—		
Commercial	914	17,460
Refined	38	1,210

Imports into Java and Madura were valued a 3,745,972 fl. (£331,500) and those into the outlyin possessions at 2,431,373 fl. (£215,000), making total of 6,177,435 fl. (£546,500) for the whole of th Netherlands East Indies. Direct imports from th United Kingdom totalled 1,165,631 fl. (£103,150) o approximately 18·5 per cent., but the imports from Singapore amounted to nearly 15 per cent. of th total, and it is probable that a considerable portion of this represents chemicals in transit from th United Kingdom. Japan supplied 30 per cent. o the total chemicals imported, a large item being sulphur pyrites (529,966 fl.) imported by th Bataafsche Petroleum Mij. for its sulphuric-acid plant at Balik Papan in Borneo. The share of the United States was approximately 25 per cent., one third of this total consisting of caustic soda and one-third of chemicals not enumerated.

Owing to the advance of scientific agriculture, the development of new plantations and the opening up of new industries, the chemical trade of the Netherlands East Indies is of growing importance. Competition for this market from Japan and the United States of America has to be considered, and Germany is already sending out agents in an endeavour to regain the trade lost during the war. United Kingdom firms are advised to send out representatives to canvass the market and be in a position to quote c.i.f. prices for immediate or forward delivery. As an alternative, much might be done by forwarding catalogues to H.M. Commercial Agent at Batavia for delivery to chemical importers, or by advertising in the East Indian Press. Catalogues and advertisements, however, would be of little value unless prices were quoted. It should be possible not only to maintain United Kingdom trade in chemicals with the Netherlands East Indies, but also to increase it, as there is every indication that the Japanese are losing their hold on the market, which is gradually favouring the United States and Germany. The names of importers of chemicals in the Netherlands East Indies and of United Kingdom advertising contractors may be obtained on application to the Department of Overseas Trade (Reference No. 9744.F.W./P.N.).

The Dutch Soap Trade in 1920.—Although in normal times soap is manufactured and exported from Holland in large quantities, there is a considerable import trade, particularly in toilet soaps. During 1920 imports declined and the export trade recommenced. Imports of various grades of soaps, together with the chief countries of origin, are given below:—

	1919. Metric tons.	1919. Per cent.	1920. Metric tons.	1920. Per cent.
cented, transparent, and liquid	604	U.K. 34, U.S. 59, Belg. 2	621	U.K. 43, Fr. 12, Ger. 11·5, Belg. 11, U.S. 10
Iard, unscented, and powder	2,348	U.K. 95, U.S. 5	691	U.K. 50, U.S. 50
Soft	31	—	70	—
Textile	12	—	6	—

The figures for 1919 include the transit trade, but those for 1920 do not; the volume of this trade is about 20 per cent. of the figures given for 1920. Exports in 1919 and 1920 were as follows:—

	1919. Metric tons.	1920. Metric tons.
Scented, etc.	216	432
Hard, unscented	2,524	3,521
Soft	130	229
Textile	—	23

The percentage representing transit trade should be added to the returns for 1920. About 75 per cent. of the exports of toilet soap in 1920 went to the Dutch East Indies, and the balance to Belgium and Germany; and of the hard soap exported, 40 per cent. went to Germany, and the rest mainly to Poland, Scandinavia, and the Dutch East Indies, in the order named.—(*U.S. Com. Rep., Mar.* 19, 1921.)

Foreign Company News.—*Brazil.*—It is reported that a large cement works is being constructed at Belem, Para, for the Companhia Para-Ceara, which intends to produce cheap cement for the reclamation work to be carried out in the State of Ceara.—(*U.S. Com. Rep., Apr.* 13, 1921.)

Germany.—The Oberschlesischen Kokswerke und Chemische Fabriken A.-G. has made a profit of 16,890,855 mk.; a dividend of 17 per cent. has been declared and 886,419 mk. carried forward (capital 6,800,000 mk.).

The net profit for 1920 of the Rütgerswerke A.-G. in Berlin was 4,802,661 mk.; 3·8 million mk. has been written off and 3 million mk. carried to maintenance account. The dividend is 15 per cent. (12½ per cent.) and bonus 150 mk. (capital 37,500,000 mk.).

With the co-operation of the Chemische Fabrik auf Aktien (vorm. E. Schering) in Berlin, the Richard Jahr dry-plate factory has been converted into a limited liability company with a capital of 2·4 million mk.—(*Chem. Ind., Apr.* 18, 25, 1921.)

Poland.—The Polish Chemical Works in Cracow (capital 50 million mk.) has begun to erect a factory at Bogumin (Oderberg) for the manufacture of saccharin and other chemical products.

A company to manufacture explosives has been founded under the name of the "Nitrat" Chemical Works (capital 300 million mk.) by the A.-G. Pocisk and the Tomaszower Artificial-Silk Works.—(*Chem. Ind., Apr.* 18, 1921.)

Sweden.—The proposal to manufacture pharmaceutical products at a central laboratory connected with the A.-B. Svenska Färgämnesindustrie in Södertälje (*cf.* J., 1921, 33 R) has been abandoned, and it is now proposed that such a laboratory be attached to the Svenska Medicinalväxtföreningen, a company which owns a large works at Ljungby. If this takes place the sale of pharmaceutical products in Sweden will become centralised.—(*Chem. Ind., Apr.* 18, 1921.)

United States.—The net profit of the Allied Chemical and Dye Corporation in 1920 was $16,179,939. A dividend at the rate of $6·33 per share has been declared on the 2,143,455 shares of common stock.—(*Oil, Paint and Drug. Rep., May* 16, 1921.)

The Manito Chemical Co. has recently completed a plant at Manito, Illinois, which is stated to be one of the largest plants for preparing natural humus in the world. It is situated on a bed containing over one million tons of humus; the product is black, completely decomposed, and contains 12—14 per cent. water and 3—5 per cent. ammonia. —(*Amer. Fertiliser, Mar.* 26, 1921.)

COMPANY NEWS.

British Cyanides Co., Ltd.—The directors announce that owing to the industrial situation they are unable to recommend the payment of a dividend on the ordinary shares. The company's works are closed owing to lack of coal, but work on the plant for the fixation of atmospheric nitrogen is being continued and nearing completion.

Jurgens, Ltd.—The profit for the year 1920 was £377,467, as against £222,040 in 1919. Including the amount brought forward the available balance is £446,280, from which £251,206 has been applied to the writing down of stocks to market value, an amount equivalent to a 10 per cent. dividend on the ordinary shares, upon which no dividend is payable. Satisfactory progress is reported at the company's factory at Purfleet.

British Cottonseed Products, Ltd.—At the first annual meeting held on May 23, the chairman stated that the company now owned the whole of the world's rights for the seed-defibrating machine (*cf.* J., 1918, 112 T, 1919, 464R), with the exception of the United States; and that it was hoped to launch the Indian company during the present year. The erection of plant and machinery in the works at Chatham had been delayed, and in view of the high price of local electricity supply, the company had decided to erect a power-plant of its own.

Cape Explosives Works, Ltd. has successfully issued £1,000,000 of 7½ per cent. first mortgage debenture stock at 95 per cent., the repayment of which is guaranteed by De Beers Consolidated Mines, Ltd. The company's works are situated at Somerset West, Cape Province, S. Africa, and its manufactures include explosives, fertilisers, sheep

and cattle dips and other chemical products. A plant has recently been completed which is able to supply the whole of the Union's requirements in detonators, and the fertiliser plant is capable of producing 70,000 tons per annum. The issued share capital consists of 500,000 ordinary shares of £1 each, all of which are held by the De Beers Company, and the profits, before allowing for depreciation and taxation, have lately been at the rate of about £146,700 per annum, but the fertiliser plant has only recently come into operation.

National Dyes, Ltd.—The first annual report and accounts covering the period December 15, 1919, to December 31, 1920, were presented to the shareholders on June 6. The report shows that 786,703 lb. of colours and 306,848 lb. of intermediates were manufactured at the company's works during that period, which is considered satisfactory, especially having regard to the fact that the trade depression necessitated the complete closing down of the factories before the end of the year. The accounts show a gross profit, after making suitable provision for decline in market value of certain raw materials, of £62,098, and after writing off £13,034 depreciation on plant, tools and machinery, £17,080 debenture and bank interest, also bad debts, etc., a balance of £6,610 is carried forward to the debit of profit and loss account.

The British Oil and Cake Mills, Ltd.—Addressing the 23rd ordinary general meeting on May 31, Mr. J. W. Pearson, chairman, said that the coal strike had entailed no stoppage of the company's operations, as practically all the boiler plants had been converted to use oil fuel, approximately 75 per cent. of the entire output being obtained by this means; and that certain of the refinery refuse could be profitably burnt in the converted plant. Except at such expensive centres as London, he was doubtful of the superior economy of oil fuel; further north, where coal could be supplied at less than half the price in London, the advantage was entirely in favour of coal. The profit and loss account for the year 1920 shows a balance of £414,464, which with £22,010 brought in allows of a total dividend of 15 per cent. on the ordinary shares, compared with 25 per cent. for 1919, when the ordinary share capital was one-half of what it is now (£2,500,000). Stocks at the end of the year were exactly the same as at December 31, 1919, but the value was assessed at one-half.

British Cellulose and Chemical Manufacturing Co., Ltd.—A progress report states that the board has adopted the recommendations made by Mr. A. Chamberlain (a director) in December last which proposed an immediate and drastic restriction of programme, including the cancellation or postponement of the delivery of much plant. The present position is that plant to produce 1 ton of silk per day is nearing completion; the daily output is about 1000 lb., and it is expected to increase this to 1 ton by the end of August. To make provision for an output greater than 1 ton per day, the sum of £278,000 has been borrowed and secured by a debenture. Any further increase in output capacity will require further cash. The directors are quite satisfied with the quality of the silk, which dyes well and gives results in many respects superior to those obtained with other artifical silks. The Post Office has approved the use of the silk for insulating purposes. Owing to the importations of carbide and other chemicals from the Continent, the carbide and other chemical departments were closed down early in the year, but it is hoped to reopen them if the Safeguarding of Industries Bill becomes law and these branches of the company's work are included within its scope. The production of non-inflammable celluloid is making good progress.

REVIEWS.

(1) Economic Mineralogy. *By* Thomas Crook. *Pp.* xi+492. (*London: Longmans, Green and Co.* 1921.) *Price* 25*s. net.*

(2) Geology of the Non-Metallic Mineral Deposits other than Silicates. Vol. I. Principles of Salt Deposition. *By* A. W. Grabau. *Pp.* xvi+435. (*New York and London: McGraw-Hill Book Co., Inc.* 1920.) *Price* 30*s. net.*

No single treatise can essay to cope with the facts and principles of so complex a subject as economic mineralogy or geology in a manner that will satisfy the needs of specialists; they have to turn to the books dealing with their specific subjects, it may be gold, zinc, oil, clay, and so on. The student who requires something more than a catalogue and less than a monograph is fairly well provided for by DeLaunay, Stutzer, Dammer and Tietze, Krusch and Beyschlag, and a goodly array of works on the genesis and distribution of ore minerals. But, judging by the recent output of such books, there is evidently a demand for a condensed practical guide to the study of useful minerals, and no book yet published in English has more successfully achieved this object or contains more information for its size than does Mr. Crook's mineralogy. Nothing, however, could illustrate more clearly than the two books under review the wide divergence that is possible in the treatment of the subject; the first is in effect a compact encyclopædia, the second is an attempt to treat one broad aspect of the subject philosophically, but with an ulterior economic motive.

(1) Mr. Crook begins with a very brief account of crystals and the general physical characters of minerals. He next explains the practical elements of crystal optics and this he does with unusual clarity. The simple chemical and blowpipe tests and laboratory methods of separation and concentration are adequately dealt with, though a little more might have been said about the employment of vertical and oblique illumination with white and monochromatic light in the study of opaque minerals in polished surfaces. Still, all this introductory matter bears the obvious mark of the experienced manipulator. The chapter on the geology of economic mineral deposits was perhaps necessary, it is of course just geology, and it was naturally impossible, in the allotted space, to give it proper treatment. In the descriptive portion of the volume the economic minerals are arranged in three groups: (1) ore minerals, (2) gem minerals, (3) miscellaneous minerals. Within each group the arrangement is alphabetical. By "ore mineral" the author means "a metalliferous mineral which owes its economic value to the fact that it is smelted to obtain a metal." This is not true, and if it were it would be misleading, for some of the metals included in this group are in practice more often extracted by electrolytic or purely chemical processes. Amongst the gem minerals are included many of little value or that are rarely employed. The miscellaneous minerals are described partly with reference to their uses, *e.g.*, abrasives, building stones, cement materials, refractories; partly in accordance with their chemical classification, *e.g.*, carbonates, sulphates, silicates, borates, and partly under common mineral names, *e.g.*, asbestos, mica, clays. This section is full of information though in an abbreviated form; it is fairly well up-to-date but, as would be expected, there is some inequality in treatment; the remarks under building stones and cement materials, for example, do not take one very far; lime is mentioned under fertilisers, but there seems to be no reference to

chemical lime. Flint is almost passed by and it is not indexed. Useful determinative tables come at the end of the book. Cross references have been carefully made and the index is satisfactory, but there are no references to original authorities. Most of the illustrations are good and new.

(2) Any work from the pen of Dr. Grabau is deserving of attention and this will doubtless be true of the one now under consideration. In the author's own words, it is "essentially a treatise on applied stratigraphy." The present volume treats of the principles of salt deposition, as deduced from the study of such deposits now forming or which have but recently been formed. These principles are to be applied in a second volume to the elucidation of the older deposits. The term salt is used with a very wide connotation. The composition of natural saline waters is reviewed together with the laws governing the deposition of salts in nature. The investigations of Van't Hoff, Walther and others and the experiments of Usiglio are discussed. Different types of deposit are examined—sea-margin deposits, formations in lakes and cut-offs, cyclic or wind-borne salts, connate salts and those derived from pre-formed rock bodies. A chapter is devoted to the concentration of salts of different kinds by the vital activities of animals and plants, another to the deposits from mineral springs, fumaroles, and circulating ground-waters. The "meta salts," that is, those formed *in situ* by metasomatic processes, are disposed of rather briefly. The interesting and difficult subject of deformation in salt bodies has a chapter to itself.

As regards the principles of salt deposition, the author rather frequently avoids giving a definite lead, preferring to quote variant hypotheses and leave the choice to the reader.

Though this is only the first instalment of a rather ambitious scheme, and the final judgment upon it must be deferred, it will be found a very handy introduction to the study of salt deposits and the distribution of the younger salt formations. The numerous outline maps and references to literature enhance its value in this respect.

J. ALLEN HOWE.

TRAITE DE LA CONSERVATION ET DE L'AMELIORATION DES BOIS. *By* M. DE KEGHEL. *Encyclopédie Industrielle. Pp.* 360. (*Paris: J.—B. Ballière et Fils.* 1921.) *Price* 10 *francs* (*bound* 15 *fr.*).

There have been very few works attempting to handle this important subject as a whole, although many papers or pamphlets have been written. In the present case the author has condensed into 360 pages of a handbook an enormous amount of information which could only be dealt with in many volumes.

The matter is divided under 18 headings or chapters. The first is historical and critical, and leads up to the final paragraph which states that a rational and complete impregnation of wood is only possible by the application of a system in harmony with a knowledge of its anatomical structure and histology. These subjects are dealt with in Chapter II which shortly goes into the cause of the circulation of the sap and the course it follows. After a few remarks on the cellular and vascular tissue and the chemical composition of wood, the author proceeds to show the difficulties in the way of thorough impregnation of all parts; and, in Chapter III, how these may be overcome. He proposes to drive out the sap by a longitudinal injection of a suitable fluid. Chapter IV describes the author's plant which provides for the immersion of the log in the fluid under the same pressure as is applied to one end, whilst the other end is open to atmosphere. This ingenious arrangement is to prevent the bursting of the wood under the high pressure necessary. Chapter V is on the selection and felling of the trees and the preparation of the logs for the special treatment, whilst Chapter VI, on the artificial ageing or senilisation of wood, is of very great interest. The changes brought about by natural and artificial ageing are explained and the reasons given for the failure of wood seasoned by the ordinary artificial methods. It describes several unsatisfactory processes which pretend to overcome these disabilities. All this leads up to the author's process of the removal of the sap and soluble constituents by forcing through the logs a weak aqueous solution of sulphoricinate of ammonia, etc., followed, after draining, by treatment with acetone. Subsequent drying in special plant results in the recovery of a very large proportion of the acetone, and the preparation of a wood which will not warp, swell or crack. The author shows that it is possible by washing to remove the hygroscopic soluble and putrescible matter from the woody structure, and that then the drying is rapid. He gives figures showing the differences in weight and time of drying of treated and untreated wood.

Chapters VII to XIII deal with fireproofing historically, chemically, and industrially. Failures are explained and the author's investigations leading up to his zinc-ammonio-phosphate solution are described.

Chapter XIV is a very long one handling the subject of wood preservation from the industrial point of view. It opens with about four pages on the causes of destruction, and then goes on to describe and criticise many of the processes which have been proposed or used for preservation. This naturally leads to the rational methods invented by the author, as exemplified by the longitudinal injection of an aqueous solution of agar-agar, formaldehyde, and ferrocyanide of potassium for railway sleepers, and a solution which will deposit sulphate of lime in the case of wood intended for paving.

Whilst the author's reasons for adopting such processes appear to be sound and to be supported by experimental data, it cannot be overlooked that he strongly condemns creosote as a preservative, making use of examples of inefficient application, and arguing that its viscosity and other disabilities make it impossible to cause it to penetrate the wood. He apparently ignores the fact that sleepers, telegraph poles, piling, and many other creosoted structural timbers have lasted much beyond their economical or mechanical life. Large fencing posts erected in 1854 are still sound. His comparative experiments with beech sleepers against white ant must be discounted. If the amount of time and care given to his agar process had been expended on the control sleepers which were creosoted, they would not have suffered.

Chapter XV is upon the colouring of wood, either to imitate others or to produce "fancy" effects. The author has given a great deal of thought to this subject, and his reasons for failures and proposals for obtaining successful results are supported by experiments. He introduces the theory of colloids to explain the unequal absorption of colouring matters, and how wood may be mordanted to render all its constituents of the opposite electric sign to that of the colouring matter. He explains how, in any haphazard mixing of colouring matters, the different viscosities of the constituents would result in selective separation in the capillaries; but he states that a complex of definite composition, more stable than either of the constituents, may be formed by mixing certain positive or basic colours with negative or acid colours.

There is a chapter on plywood, compressed wood, and bent wood, and finally, one on the installation of plants suitable for carrying out the author's ideas.

The diagrams and reproductions of actual plant are badly printed; otherwise the perusal of the book has been one of pleasure and instruction. It is to be regretted that the author has said little or nothing about the great plants of England and America, or of the large amount of work of investigation carried out by the American Wood Preservers' Association and others. This may be accounted for by the fact that most of these plants use the creosote process.

HUBERT FERGUSSON.

RED LEAD AND HOW TO USE IT IN PAINT. *By* A. H. SABIN. *Third edition, rewritten and enlarged. Pp.* xi+139. *(New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.* 1920.) *Price* 11*s.* 6*d. net.*

This work is mainly intended for the use of constructional engineers, architects, and others who have to deal with the protection of iron from rust. The author lays great stress upon the utility of red lead for this purpose, and he rightly points out the importance of the fineness of division of the red-lead particles, so that a most homogeneous paint-coating may be obtained. A great deal of importance is attached to the amount of litharge present, and the author advises the use of a pure red lead because it is found that on keeping as a mixed paint the litharge causes "livering," or if much be present the paint may even set hard; in any case such paints cannot be spread evenly. The exact reasons why pure red lead (Pb_3O_4) should be superior to other pigments as a protective coating for iron are not made clear; the author, as stated, insists upon its fineness, but does not say why any equally fine inert pigment should not do as well. Although the presence of much litharge is condemned, some may be added, if desired, under special circumstances to a 98 per cent. red lead paint. The reviewer is of the opinion that insufficient importance has been attached to the character of the oil binder used for thinning (*cf.* Ingle and Woodmansey, J., 1919, 101T); but the mention of the sand blast as a means of cleaning rusted surfaces either for painting or repainting is a welcome suggestion; it has been used in America for some time, but does not seem to have found sufficient application in Europe. The book is embellished with numerous photographs of bridges, steamers, etc., which seem to serve little useful purpose, but as the volume is written in a popular style, it is suitable for the people for whom it is intended.

THE RELATIVE VALUE OF THE PROTEINS IN NUTRITION.

R. H. A. PLIMMER.

Complete hydrolysis of the protein to its constituent 18 or 20 amino-acids occurs during digestion in animals; the amino-acids circulate in the blood and reach the various organs, which build new tissue from the units. Animals have been maintained on a diet containing as its protein content a mixture of pure amino-acids in suitable proportions. Biologically, the proteins must therefore be regarded as mixtures of the various amino-acids, digestion and absorption as a re-shuffling of the units. The amino-acids are not convertible into one another, nor capable of being synthesised by the animal organism, with the exception of glycine, which, under certain conditions, can be formed in the body. The different proteins have different compositions, thus, for example, casein contains 3 per cent. of glutamic acid and gliadin 40 per cent. Some proteins are complete, *i.e.*, contain all the amino-acids, others are incomplete and lack certain units. It can thus hardly be expected that proteins should have the same value in nutrition. Some of the amino-acids may be indispensable, others not so essential. There are two main problems to study in nutrition: the formation of new tissue, as in the growth of young animals, and the maintenance of tissue, which undergoes so-called wear and tear, in adult animals. The problem is ultimately to find out the function of each amino-acid in growth and maintenance.

The effect of the absence of certain amino-acids.

The most certain way of studying the problem is to feed animals upon known mixtures of amino-acids, but the practical difficulties are far too great. The amino-acids are not easily prepared, and it is almost impossible to obtain sufficient of each of them to feed an animal, even a mouse, for any length of time. Two other ways are possible:—(a) to feed incomplete proteins and add the missing unit or units; (b) to feed completely hydrolysed proteins, *i.e.*, a mixture of amino-acids from which one or more units have been removed by chemical means.

The first experiment of this kind was made by Willcock and Hopkins in 1906. Zein was chosen as incomplete protein and fed to mice: in one set alone, in another set with the addition of 2 per cent. of its amount of tryptophan. Failure occurred in both sets of animals, but not so rapidly in those on zein and tryptophan. Young mice with zein alone died generally in 16 days; with zein and tryptophan in 30 days. Adult mice without tryptophan lived 27 days, with tryptophan 49 days. The survival period was thus appreciably lengthened by the presence of tryptophan. The failure to live was most probably due to the absence of other units from the zein. Ackroyd and Hopkins repeated the experiment in 1916 by the second method of experimenting which offers better conditions. The animals were fed upon a mixture of the amino-acids from casein. This mixture does not contain tryptophan, since it is destroyed by acid hydrolysis. In the first period tryptophan was added; on the 12th day it was omitted and introduced once more on the 35th day. The animals continued their growth during the first period, declined in weight during the second period, and grew again in the third period when the tryptophan was present.

Osborne and Mendel in America have made numerous experiments with various pure isolated proteins of known amino-acid composition. Their most important results in this connexion were with wheat gliadin; this is a complete protein, but has very little lysine. Adult rats were maintained for long periods on this protein—as long as 500 days—but young rats, though they lived for long periods, failed to grow. The authors therefore regarded lysine as essential for growth. Later, they showed that if they added lysine at definite intervals to the food containing gliadin as sole protein, growth took place with the lysine, but not without it. The minimum amount of lysine necessary to produce normal growth was found to be between 2 and 3 per cent. of the amount of protein in the diet.

The value of lysine for growth was shown in a more practical way by Buckner, Nollau and Kastle. They fed chickens on a poultry farm on diets of high and low lysine content. Their figures and photographs definitely showed more rapid growth on the mixture of high lysine content.

The two other hexone bases—arginine and histidine—are essential units of proteins. As shown by Ackroyd and Hopkins, their removal from the hydrolysed casein mixture leads to loss of weight of the animals; if only one is absent from the food the rate of growth is lessened, so that it appears as if these two units were inter-related. The structural formulæ of these compounds suggest a possibility of the conversion of the one into the other by the wonderful mechanisms of the animal body. These two units were found to give an increase of allantoin in the urine of the animals; thus we know that the purine ring can be synthesised from them. This synthesis by animals has long been suspected, as young birds and animals produce purines on a diet with an almost complete absence of purine compounds.

It is more difficult to arrive at the function of the amino-acids containing aromatic nuclei. Some proteins lack tyrosine, but all contain phenylalanine, which is very difficult to remove from a mixture. Phenylalanine and tyrosine both give rise to homogentisic acid in cases of *alkaptonuria;* phenylalanine may therefore be oxidisable to tyrosine in the body. The almost complete removal of tyrosine from the mixture from casein made no difference to the growth of rats, as shown by Totani. The amount of phenylalanine in the mixture was thus probably sufficient to supply the need for aromatic nuclei. According to Abderhalden, tyrosine cannot be dispensed with.

Cystine is the only unit which contains the element sulphur, though another sulphur-containing compound may be present in proteins. The amount of cystine is not known except in a few cases, but it is estimated from the sulphur content. The need of cystine in the food has been shown most conclusively by experiments with phaseolin, the protein of the navy bean. Slow growth resulted on a diet with the protein alone, but normal growth followed the addition of 2 per cent. of its amount of cystine. Very little sulphur is present in casein. Osborne and Mendel found that less casein was required in a diet if it were augmented with cystine: 15 per cent. casein alone gave normal growth, but 9 per cent. if cystine were added.

It is not possible to test a protein without proline, but arachin with only 1·4 per cent. was tried by Sure. This protein failed to give normal growth even after the addition of extra proline, so that its deficiency must be caused by another missing substance. It is possible that proline and glutamic acid are related units in the molecules of the proteins.

An experiment has also been made to see if the animal organism can introduce an amino group into the molecule of nor-leucine and convert it into lysine. Animals fed upon gliadin and nor-leucine did not grow just as on gliadin alone. The synthesis is thus not possible.

The whole group of simple mono-amino-acids has yet to be tested. They may not all be necessary. In cases of diabetes several can give rise to glucose; their function may be to supply energy through their conversion into sugar. Isoleucine is absent from gelatin, as recently shown by Dakin; this may be another reason for the failure of gelatin in nutrition, which is usually attributed to the absence of tyrosine, cystine and tryptophan.

Comparative nutritive value of proteins.

Few proteins show such marked deficiencies as gelatin, gliadin and zein. The different amounts of the units in complete proteins make little difference to growth if the diet contain *abundance* of protein. Growth is observed on the most varied proteins of animal and plant origin; but if any *restriction* in the amount of protein in the food be made, then the growth is lessened or inhibited. Each complete protein will thus have a definite minimum for growth. Two per cent. lactalbumin gave maintenance, 4·5 per cent. growth; 2 per cent. edestin scarcely gave maintenance, 4·5 per cent. slight growth; with other proteins 2 per cent. led to loss of weight. With a protein content of 4·5 per cent. the best growth was with lactalbumin, followed by edestin; there was no growth with casein unless supplemented with cystine, or with glycinin or squash-seed globulin. An experiment showed that a food with 9 per cent. of lactalbumin was equal to one with 12 per cent. of casein or with 15 per cent. of edestin.

The nutritive value of the proteins of legumes, nuts, etc.

The legumes contain large amounts of protein, and the chemical analysis of the proteins shows no abnormality. The proteins of the pea have been found inadequate by McCollum; it is probably due to lack of cystine, for, as stated above, phaseolin is supplemented by cystine.

The soya-bean protein is of good quality for normal growth, so also are the proteins of the pea-nut. The latter are peculiar in their high lysine content. The proteins of these foods require cooking so as to make them capable of being digested and assimilated.

The edestin of hemp-seed and cotton-seed is not a perfect protein with its high arginine and glutamic-acid content, but the foodstuff is largely used in America as cattle food. Its poisonous constituent can be removed by steaming or by the hot method of oil extraction.

Nut proteins have a high value on account of the high proportion of hexone bases which they contain. Normal growth has been observed on coconut press-cake, walnut, filbert, pine nut, and other nuts. Experimental work has thus confirmed the assertion of fruitarians of the high value of nuts in nutrition.

The nutritive value of the mixture of proteins in cereals.

Though the gliadin group of proteins of cereals is not adequate as source of protein in the food, it does not follow that the mixture of proteins in the grain is likewise insufficient. Wheat and maize glutenins as sole protein have been found satisfactory for growth, and may compensate for the inefficiency of the gliadins. The whole grain contains also small quantities of an albumin, globulins, and proteose. Particular attention has been paid to the nutritive value of cereals. The results are not altogether consistent; the discrepancies seem to be due to the different basal diets used by the various investigators. The results of McCollum and associates are very contradictory; they believe the inadequacy depends on improper mineral supply. Insufficiency of vitamin supply is a contributory cause. Osborne and Mendel tried not only the whole grain, but also different commercial articles produced by milling, such as wheat flour, bran, embryo. Normal growth followed the use of whole grain, and very little difference was noticed among the various grains.

In all cases animals kept for long periods produced small or no litters of young; their health had thus been impaired. This loss of reproductive power has been observed by all workers if cereals supply the sole protein.

Wheat embryo contains the albumin, and is fully adequate; bran proteins are even of superior value. Wheat flour, pearl barley, and maize meal are not adequate.

The milling process thus removes "good" protein. Wheat flour, etc., does not contain enough total protein, but in the experiments the total was made up by adding gluten. The endosperm of the grain will only furnish protein for maintenance.

Supplements to the proteins of cereals.

Neither men nor animals consume the whole cereal, and as the endosperm does not supply enough protein in quantity or quality, it must be supplemented. The protein ratio of 1:10 needs to be increased up to 1:5. Animal proteins form the best supplements. Lactalbumin was shown by Osborne and Mendel to be the best supplement, but for some peculiar and unaccountable reason other workers do not find this protein so good. Meat, milk, eggs are almost equally efficient, but casein is of less value. In the case of maize meal and milk at least an equal part of skim milk is needed; this gives 30 per cent. of the mixture of proteins as derived from milk. Yeast protein and peanut flour are good supplements. Cottonseed and pea are inferior, whilst products like distillers' grain or vegetable albumin, which is derived from grain, are of little value. The best supplementing proteins are thus those containing the hexone bases, tryptophan, etc. which are low in amount in the cereals.

To produce normal or rapid growth it is possible that it may be more economical to use "good" proteins, which are more expensive than "bad" proteins.

Quality of protein in milk production.

Diet plays a large part in milk production. Quantity and quality of protein are the chief factors. Since neither the animal body nor the mammary gland can synthesise amino-acids, the food must contain sufficient for the manufacture of casein and lactalbumin. Hart and Humphrey have paid some attention to this question. A high milk yield of 27 lb. requires a protein ration 1:4·5; 1:6·7 is necessary for 11 lb.; 1:8·5 is not economical. If the animal is not furnished with sufficient protein it produces milk from its own tissues. Skim milk has an efficiency of 65, against 25 of a mixture of maize and alfalfa. Gluten feed (maize embryo) has 45, flax seed 61, casein 59, milk powder 60. A comparison of clover and alfalfa on the same basal diet showed a superiority of alfalfa for high milk production for 16 weeks. With another basal diet the reverse may be the case. The value will depend on the proportions of the amino-acids in the food and their correspondence to the proportions in the milk proteins. No guide is at present available from the side of chemical analysis. Little is known of the proteins of grasses and green foods. The nearest approach to the proteins of cow's milk are the proteins contained in the milk of other animals. If the milk proteins of all animals are the same in composition, the milk of one animal will be as good as that of another animal, but if not, as is most likely, the best source is the animal's own milk. Cannibalism has been proved to be the best method of feeding dogs. We approach cannibalism in the nursing of the young

on mother's milk. Milk contains ultimately the proteins of the mammary gland.

Proteins and pellagra.

The primary cause of the disease pellagra appears to be quality of protein, but at the same time insufficiency of protein together with improper salt supply may play a part.

Pellagra was not recorded in Europe before the introduction of maize into Spain by Columbus. The disease spread to France, Lombardy and eastwards, wherever maize was extensively used for food. Roussel (1866) cured it by good food, and advanced cases have been successfully treated by a generous diet (Lorentz, 1914; Willets, 1915). Goldberger cured and prevented the seasonal appearance of pellagra in lunatic asylums by increasing the meat and milk in the diet, which had previously been very deficient in this respect. Goldberger produced the disease experimentally in a squad of volunteers by a diet consisting of vegetable protein, mainly wheat, maize and rice. On a vegetable diet principally of maize, Chick and Hume produced symptoms in monkeys very like the symptoms of pellagra in man, and a cure was effected in one case by a diet containing better proteins.

Wilson, of Cairo, who investigated the outbreaks of pellagra in Armenian refugee camps at Port Said, found the diet was inadequate in energy supply and protein supply (vegetable). Thomas (1909) tested the comparative values of proteins for man, and found that meat was three times as good as maize. Wilson, calculating from Thomas' figures, determined that the refugees had a casein equivalent of 22 gm. per day. On improving to a casein equivalent of 41 gm. per day no more cases of pellagra occurred. Shortage of protein and quality of protein are thus at the root of the trouble.

IRISH PEAT.*

The Peat Inquiry Committee was established to inquire into and consider the experience already gained in Ireland in respect of the winning, preparation, and use of peat for fuel and for other purposes; to suggest what means shall be taken to ascertain the conditions under which in the most favourably situated localities it can be profitably won, prepared, and used, having regard to the economic conditions of Ireland; and to report to the Fuel Research Board.

Particulars of the quantity of peat produced per annum and of the peat resources of Ireland have been given previously in this Journal (*cf.* J., 1920, 213 R). From the investigations of the Committee it is apparent that if air-dried peat is to be produced at the rate of 300 to 500 tons per day, automatic machines of the Wielandt, Baumann, Persson, Jacobson, or Moore type will have to be used. By using such machines instead of hand-winning, the number of men required will be reduced to one-fourth, although the number of women and children will be slightly increased. It is possible also that a longer season could be worked with peat-machines than without, as the men working the machines can be protected from the weather. Night-work might also be undertaken, as cheap electric light would be available. Machine-cut peat dries more regularly than slane-cut peat, is less affected by rain and recovers more rapidly from its effect. This results in quicker drying and offers the possibility of drying more peat per unit area of drying ground than when hand methods are used; and this would lead to greater economy in collection. Machine-cut peat shrinks more than slane-cut peat, with a resulting increase in density, and hence less volume is required for equal calorific value. The volume for equal calorific value may be reduced from 5½ to 4 or even to 3½ times that of coal. Machine-cut peat, owing to the breaking down of the original structure, has a more uniform distribution of the fibres, is less brittle and is better able to stand handling in transport. Peat-machines can cut for the whole depth of a deep bog, so that a more uniform material is obtained, which is very important for gas-producing or steam-raising. It is estimated that one acre of bog will yield 2600 tons of air-dried peat (25 per cent. water), and hence an output of 100,000 tons would involve the cutting away of about 38 acres per annum. To make provision for about 100 years, such a scheme would require some 3800 acres of bog or 5000 acres of land, allowing 1000 acres for the necessary drying-ground and 200 acres for room for working the peat-machines, transport and stacking. To win mechanically 100,000 tons of air-dried peat and deliver it at a distance not exceeding, say, 3 miles from the bog, would require approximately 130 men and 400 women and children for a season extending from February to the end of September. For the remainder of the year only about 35 men would be required for transport.

The Committee recommended that the State purchase a large bog of at least 10,000 acres, and provide four electrically-operated peat machines of the automatic dredger, macerator and transporter type, together with appliances for collecting, stacking and loading, and narrow-gauge tracks with electric locomotives and wagons. It also advised the erection of an electric power-station of at least 500 kw., using peat fuel and supplying power for the machines and transport. It was recommended that the bog be prepared by main drainage, by local drainage for peat-winning and local drainage for agriculture, and also that the necessary housing be provided for the employees, and office and laboratory accommodation be found. The Fuel Research Board intimated its willingness to direct the work of an experimental peat-station in Ireland and, whilst not committing itself to any definite policy, suggested as a broad programme the purchase by the Government of a suitable bog area, the establishment on that area of an agricultural colony under the control and management of the Irish Department of Agriculture, the establishment of an experimental station on the bog area under the control of a deputy director to be appointed by the Fuel Research Board, and the appointment of an Irish Advisory Committee in connexion with the station. The Board's contribution to such an establishment would be limited to buildings and machinery (£34,000), plus £6000 for contingencies, plus running expenses for 4 years (say £14,000), making a total of £54,000.

An agricultural sub-committee appointed by the Department of Agriculture and Technical Instruction for Ireland reported that an agricultural colony is not, and cannot be, complementary to a scheme for the mechanical winning of peat fuel, and that the reclamation of virgin bog would not be remunerative under the most favourable conditions, although the reclamation of cut-away bog might be remunerative provided (*a*) that the cut-away bog afforded facilities for drainage, (*b*) that a sufficient depth of peat were left by those in charge of the peat-fuel winning operations, and (*c*) that either the stratum underlying the peat residue consisted of suitable mineral matter, such as marl, limestone, gravel or clay with an admixture of sand, or that one or more of these materials were present in close proximity to the cut-away bog.

* The Winning, Preparation, and Use of Peat in Ireland: Report and other Documents. *Fuel Research Board, Department of Scientific and Industrial Research. H.M. Stationery Office*, 1921. Price 1s. net.

The sub-committee was also very sceptical as to the cost of the bog, the cost of housing the labour, cost of live-stock, implements, and incidental expenditure on roads, fences, etc.

Prof. Pierce Purcell has been appointed Peat Investigation Officer to the Fuel Research Board, and further inquiries and research are proceeding.

SOCIETY OF CHEMICAL INDUSTRY.

ANNUAL MEETING, 1921.

SULPHURIC ACID IN CANADA.

Those who follow the development of Canadian chemical industry, and in particular those who are attending the Annual Meeting in Montreal, will be interested in the following short history of the manufacture of sulphuric acid in the Dominion.

Following the discovery of petroleum in the Ontario peninsula in 1868, plants were erected at Hamilton, Woodstock, London, and Petrolea, Ontario, and realising the economy of producing the acid in close proximity to the oil refineries the Canadian Chemical Manufacturing Co. built the first sulphuric-acid works at London. The plant was initially quite a small one, compared with such plants to-day, and consisted of one sulphur burner of the Blair type, two lead chambers, and a concentrating system of lead pans with about twenty glass bottles which were termed retorts. The point of desired concentration was determined by the appearance of white fumes over the surface of the acid, or by observing the clarification produced after adding a pinch of sawdust. Under this treatment the acid first became black, but on attaining a specific gravity of 1·825 it became transparent. This was indeed a crude and inexact method, but it accorded with the practice of that time. Sicilian sulphur was the raw material employed and the amount of acid produced was from 50 to 60 tons per month. When manufacturing first began the water necessary for the reaction was placed in the bottom of the chambers, and this method was followed for several months before the idea of supplying it as injected steam was introduced. As might be expected this was followed by a much larger yield of acid. Not long after, pyrites was used instead of sulphur. The plant was destroyed by lightning a few years later, and when rebuilt on a larger scale the burners were converted to the sulphur type. In 1887 the factory was burned down, and rebuilt with three lead chambers, each 120×20×18 ft., which were not housed in buildings as their predecessors were. The retort system of concentration, in which breaks were frequent, was superseded and improved by the use of the Faure and Kessler type, and production was increased to about 10 tons per day. The factory was dismantled and removed in 1904.

The second Canadian plant was built in 1870 by an English syndicate which purchased land at Petrolea and London, Ont., sank oil wells, and erected at London an oil-refinery and sulphuric-acid works known as the Ontario Chemical Works. The plant consisted of two small chambers with glass-retort concentration and produced from 35 to 40 tons per month; it was absorbed by the company mentioned above, and in 1888 was dismantled.

In the early 'seventies, when pyrites was discovered within about four miles of Brockville, Ont., the Brockville Chemical Co. erected a plant of four chambers, but before actual manufacturing began the buildings were blown down by an unprecedented wind. After being rebuilt the plant worked successfully for a few years, but its career came to an abrupt end owing to the pyrites deposits becoming exhausted.

The Nichols Chemical Co. built a large plant at Capleton, Quebec, about the year 1887, and in 1895 the Victoria Chemical Co. established a plant at Victoria, British Columbia, which is still in existence, and produces acid of 60° B. In 1901 the Dominion Iron and Steel Co., then known as the Dominion Coal Co., started a small plant at Sydney, Nova Scotia, which was replaced by a larger one in 1911. In 1906 the chamber system of the Nichols Chemical Co. at Capleton, Que., was replaced by the contact system. Other contact plants were established by the same company at Sulphide, Ont., in 1907 and at Barnet, British Columbia, in 1909. These are the only contact plants in operation in Canada at the present time. In 1911 the Graselli Chemical Co. erected a chamber plant at Hamilton, Ont., which concentrates the acid to 66° B. by the cascade system. In 1912 the Algoma Steel Corporation, of Sault St. Marie, Ont., erected a Faulding high-chamber plant to manufacture sufficient acid to sulphate the ammonia in its coke-oven gas. This plant is also still operating. Other acid plants of more recent date include that of the Consolidated Mining and Smelting Co., at Trail, British Columbia, built in 1916, and during the war the Aetna Chemical Co. erected a chamber plant at Drummondville, Que., which may be dismantled. The Chemical Products, Ltd., has a plant at Trenton, Ont., which was taken over from the British Chemical Co. after the war and now specialises in the production of acid phosphate.

NEWS FROM THE SECTIONS.

SHAWINIGAN FALLS.

On May 25 Dr. G. S. Whitby, assistant professor of chemistry, McGill University, gave an address on Rubber to the members of this Section.

At the outset the lecturer drew attention to the rapid growth of the rubber-plantation industry during the decade 1909–19, the total production of raw rubber having increased about sixfold, and that of plantation rubber from approximately 3000 to 300,000 tons per annum. Methods of preparing plantation rubber were outlined. Special attention was drawn to the important influence on vulcanisation of the small amount—about 5 per cent. in all—of non-caoutchouc substances present in the raw rubber, the influence of the resin being particularly marked when the rubber is compounded with litharge. Reference was made to the investigations now being conducted at McGill University on the chemical nature of the rubber "resins."

With the aid of lantern slides, the processes employed in the making-up and vulcanisation of rubber articles were outlined. The influence of the chief compounding ingredients was considered, the growing importance of organic accelerators of vulcanisation being emphasised. Data were given showing that such accelerators may not only increase the speed of vulcanisation, but that they may also confer improved physical properties on the vulcanisates; and further, that different accelerators may exercise favourable effects in different directions, *e.g.*, one may improve tenacity whilst another improves extensibility. Mention was made of the work of Wiegand on the influence of inorganic compounding ingredients.

The uniqueness of the mechanical properties of vulcanised rubber was brought out by consideration of the stress-strain curve, of the magnitude and character of hysteresis and elastic after-effects in

rubber, and of the relation between thermal and tensile effects. Experiments illustrating these effects were shown.

LONDON.

At the meeting held on June 6, Mr. J. L. Baker presiding, a paper entitled "Industrial Respirators," by Dr. L. Levy and D. W. West, was read by the former.

A respirator consists essentially of two parts: a face-piece and an absorption apparatus. The face-piece may consist only of a mouthpiece and nose-clip, but this form causes much discomfort and affords no protection to the eyes. The second and more recent form is a complete mask of rubber fabric with eyepieces of "Triplex" glass so arranged that the incoming air passes over the inner surface of the glass, thus preventing dimming by moisture from the breath. This form requires neither the use of a mouthpiece nor of a nose-clip, and may be worn for a much longer period than the former type. The purifying canister is of the form used in the small military box-form respirators, and the substances employed for absorption should have a high capacity and rate of reactivity for the gases to be removed from the inspired air. The absorbents used vary according to the toxic substance to be dealt with; crystallised copper sulphate, highly activated charcoal, and a mixture of alkali and charcoal powder are used, respectively, for ammonia, hydrocarbon and other neutral gases, and acid gases. A satisfactory means of removing smoke and solid particles is a mask of fine felt fitted with an efficient non-return valve for the egress of the expired air. No absorbent for carbon monoxide is known which is suitable for use in a respirator, and, therefore, the catalytic oxidation of this gas by oxides is employed. But this method has certain disadvantages, *e.g.*, the harmful effect of moisture upon the catalyst (which may be overcome by a preliminary passage of the gases through calcium chloride), the absorption of a portion of the atmospheric oxygen to oxidise the carbon monoxide, and the absence of any indication of failure in the respirator. The last-named defect may be remedied by using an upper layer of iodine pentoxide and sulphuric acid which, when any carbon monoxide unoxidised by the catalyst is absorbed, liberates free iodine vapour that acts upon the throat of the wearer and thus indicates the breakdown of the purifying medium. The tests used in determining the efficiency of different forms of respirator were described.

Professor K. G. Naik then read a paper on "The Gold and Silver Thread Industry of India," which prior to the war had become nearly extinct owing to the dumping of German-made material upon the Indian markets. During the war this source of supply was cut off and the native industry resuscitated. Most of the work is done by hand—the little machinery that is employed is of a primitive kind. Silver bars, 9 in. long by 3 in. square, are coated with 0·5—1·0 per cent. of gold by hammering, and the bars are further hammered out to a length of thirty inches. The resulting rods are then pulled through a series of draw-plates until each ounce is converted into a fine wire some 2000 to 4000 ft. long. After polishing on a pad of leather or cloth, the wire is flattened into ribbon by passing between rollers, and is then wound into a helix upon a rotating needle, or wound spirally around cotton or silk threads. Spangles are produced by cutting the helix lengthwise and beating the rings so obtained with a special kind of hammer. A method devised by the author for plating the fine silver wire by electro-deposition in a gold-cyanide bath was described, and lantern slides of various stages in the manufacture as well as numerous samples of the different products were exhibited.

MEETINGS OF OTHER SOCIETIES.

THE PHYSICAL SOCIETY.

At the meeting held on June 10, Sir Ernest Rutherford lectured on "The Stability of Atoms."

The study of the scattering due to α particles has led to the view that the atom consists of a minute positively-charged nucleus surrounded by a number of rings of negatively-charged electrons. A direct verification of Moseley's law (the nuclear charge is represented by the atomic or ordinal number of the atom), to an accuracy of about 1 per cent., has recently been given by Chadwick for the elements copper, silver, and platinum. The atomic radius of the atom of a heavy element such as uranium (ordinal number 92) is of the order 10^{-8} cm., and the corresponding nuclear radius is 7×10^{-12} cm.; in the case of lighter elements, such as helium, the nuclear radius is about 3×10^{-13} cm. The only promising line of attack whereby a permanent effect may be produced upon the atomic structure of an element appears to be that afforded by the impact of swiftly moving α particles with the atomic nucleus; no permanent effect upon the atomic structure is to be anticipated from effects produced in the rings of negatively-charged electrons. The great stability of the atomic structure arises from the minute dimensions of the nucleus, and the manner in which the nucleus is guarded by the rings of electrons. It is, however, possible by the bombardment of swiftly moving α particles to effect an occasional collision of the particle with the atomic nucleus of an element, more especially a gas, and in this manner, the lecturer has shown that in the bombardment of nitrogen, hydrogen is apparently ejected from the nucleus. The nature of the ejected particle is ascertained from its range of ejection. Recently the method has been extended to the heavier elements such as aluminium, and the surprising result has been obtained that in such cases and also in the case of nitrogen, particles are ejected having a range greater than 80 cm., the range of ejection of the hydrogen particle being 28 cm. The possibility of the ejected particles being due to contamination with hydrogen is definitely ruled out by the method of experiment. Thus the possibility of attacking the nucleus has been advanced a stage, and the lecturer concluded by remarking that the recent work of Shimizu has shown that the nucleus would be very readily disintegrated, with the liberation of prodigious atomic energy, provided the α particle were able to approach sufficiently near the atomic nucleus.

THE ROYAL INSTITUTION.

Sir J. J. Thomson delivered the Friday Evening Discourse on June 17 on "Chemical Combination and the Structure of the Molecule." After a brief review of the electron theory, the lecturer outlined his theory of atomic structure. In this it is assumed that the force between the central positively charged nucleus of the atom and the electrons is not in accordance with the inverse square law, but assumes a series of periodic attractive and repulsive values as the distance apart increases. Eight is then the greatest number of electrons that can be in stable equilibrium without reproducing electronic distributions characteristic of atoms containing fewer electrons, a result in accordance with the Periodic Law. It was pointed out that the periodicity of atomic sizes as deduced from this theory was in accord with the results of the experiments of Bragg but differed somewhat from the periodicity as exhibited in Lothar Meyer's table. The theory indicates the possibility of the formation

of compounds of the inert gases. Chemical combination between two atoms is supposed to occur as the result of the coalescence of the cellular structures of electrons and positive nucleus constituting the atoms. This coalescence may be effected in more than one way. A ready explanation is thus afforded of the existence of, *e.g.*, a combination of carbon and oxygen both as carbon monoxide and as the radicle=CO. The arrangement of eight electrons at the corners of a cube with a positively charged nucleus at the centre constitutes an essentially stable system. Such cubes can be combined geometrically in a variety of ways of which two were instanced by the lecturer. In the first, the cubes are combined so as to have a face in common, and in the second a side is common to them. Analysis shows that the second is the more stable arrangement, and in this manner is explained the existence of the very extensive series of carbon chain compounds of the generic formula $(CH_2)_n$, compounds of this type being known up to the value n=60. The series formed by cubical structures having a face in common is a very restricted one and is known only up to C_3H_4. The benzene ring contains thirty electrons, each carbon atom containing four and each hydrogen atom one. To constitute such a ring from six cubical structures of eight electrons requires eighteen electrons to be held in common. Clearly this can be effected by constituting the structure of six cubes having alternately a face and a side respectively in common. Such a mode of constitution affords an explanation of the existence of alternate single and double bonds between successive carbon atoms in the benzene-ring structure. In this connexion it was pointed out that theory led to the conclusion that the equilibrium figure of eight electrons about a central positive nucleus was not a cube but what might be termed a "twisted cube" formed by twisting one face through half a right angle relative to the opposite and parallel face about an axis perpendicular to the faces. A symmetrical benzene-ring structure would result from the coalescence of *triangular* faces of six such twisted cubes, whereby the economy of eighteen electrons in the structure would be effected in a uniform manner.

At the conclusion of the lecture, the Duke of Northumberland, president of the Institution, presented on behalf of the members a gold loving cup to Sir James and Lady Dewar on the occasion of their golden wedding.

THE ROYAL SOCIETY.

At the meeting held on June 16, a paper entitled "The Ratio of the Specific Heats of Air and of Carbon Dioxide," by Prof. J. R. Partington, was communicated by Dr. J. A. Harker.

The ratio of the specific heats, $\gamma = c_p/c_v$, was determined by the method of adiabatic expansion. The gas was contained in a 120-litre vessel, and the temperature-change immediately after expansion followed by a platinum thermometer, with compensating leads of wire 0·001 mm. diameter, the resistance of which was observed by an Einthoven string galvanometer of 0·01 seconds period. The fundamental temperature measurements were made with a mercury thermometer. The results were calculated by the characteristic equation of D. Berthelot, so that deviations from the ideal gaseous state were allowed for. The final results, which are believed to be accurate to 1 part in 1000, are: γ for air at 17° C.=1·4034; γ for carbon dioxide at 17° C.=1·3022. From these numbers the specific heats of the gases were calculated by Berthelot's equation, with the following results: c_v for air at 17° C.=0·2387 cal.; c_p for carbon dioxide at 17° C.=0·1996 cal. All the values refer to atmospheric pressure.

SOCIETY OF GLASS TECHNOLOGY.

The last meeting of the session 1920–21 was held in the University of Sheffield on June 15, Dr. Morris W. Travers presiding. Dr. P. G. H. Boswell, professor of geology in the University of Liverpool, was elected the first honorary member of the Society.

A discussion was then held on "Oil-firing in the Glass Industry." The president showed by means of thermochemical calculations that the fuel efficiency of a furnace in which the oil was burned with air at the ordinary temperature, and that of a furnace in which coal was first gasified by air with only little steam, the gas being burned with air at the ordinary temperature, were practically identical. That non-regenerative glass tanks fired with oil were preferred to those fired by gas was probably due to the fact that small gas-fired tanks were inefficient. In oil-firing practically the whole of the air could be preheated, but in gas-firing only the secondary air could be preheated, so that a regenerative oil-fired furnace was more efficient than a furnace in which the secondary air was preheated. Other conditions being equal, the ratio of the efficiency of the oil and gasified-coal systems was as 1·37 to 1. Neglecting other factors, the results might be summed up as follows:—

	Net calorific value.	Cost in London per ton.	Efficiency of combustion.	Relative cost.
Oil	10,500 ..	105s. ..	1·37 ..	1·20
Coal	7,420 ..	45s. ..	1 ..	1

Mr. J. Connolly remarked that he had run an oil glass-furnace for four years, which had worked with fewer breakdowns and stoppages than any other method. At the end of that period, however, the price of oil was raised and its use was abandoned. The adaptability of oil to glass work had been demonstrated and was past argument, but he did not think they would get a higher efficiency with oil than with coal so long as there was a great difference in price.

Mr. J. H. Steele thought that oil had not been given a fair chance in the glass industry; his experience of it was very satisfactory. It was unusual, however, to find a glass furnace properly adapted to oil-consumption. He had known better results to be obtained from the use of crude oil or creosote than from fine petroleum of high calorific value, a fact which indicated that the furnaces in use were not satisfactory.

Mr. F. G. Clark spoke of the use of "glory holes" fired by oil. The best results were obtained from crude creosote oil, partially heated, and compressed air at about 15 to 20 lb. per sq. in. In making 8-ounce bottles on a 7½ hour shift some 3·92 gallons of oil were used, at a cost of 4s. 3d. per shift. When two chairs were working at one "glory hole," the cost was about 2s. 2d. per shift. Gas did not yield the temperature desired, and creosote oil gave a fuller and "fatter" flame than petroleum. Consequently the neck of the bottle was heated up more uniformly and the product had a better "finish."

Mr. G. Lawton described a simple oil-burner that had yielded good results. In one power-station one ton of oil was apparently equivalent to about 2½ tons of coal.

Mr. J. Venn Stevens pointed out the advantages of oil-fuel for glass furnaces. It was clean in use, the flame came into direct contact with the glass without producing any discoloration or deterioration, and a uniform temperature could be maintained.

Mr. A. Bayliss remarked that the "Aquitania" had in the stoke-hole 350 men when fired with coal, but only 84 with oil-fuel. With solid fuel the efficiency might range from 50—65 per cent., but with oil-fuel it might be as high as 85 per cent. In addition, ignition and extinction were instantaneous. The freedom from sulphur in the gases

formed by combustion was an important point for glass workers.

Mr. W. H. Casmey referred to the very great potentialities of oil when mixed with inferior qualities of solid fuel. In one case, by taking 3 tons of coke breeze (at 12s. 6d. per ton, calorific value 10,000 B.Th.U.) and one ton of oil-fuel, a fuel of 12,000 B.Th.U. was obtained costing 37s. 4d. per ton, capable of giving an evaporation of 530 lb. per 1s., or nearly 2000 lb. more evaporation per ton than with coal at 40s. per ton.

Mr. W. J. Rees thought it was very necessary to obtain reliable data showing how efficient coal-firing compared with efficient oil-firing.

Prof. W. E. S. Turner exhibited and explained a diagram showing the proposed design of a combustion-chamber for the oil-firing of a glass tank furnace. He also read a communication from a firm in which it was stated that there were very few oil-fired pot furnaces in this country. The few that had been tried had not been entirely successful, the chief trouble being the cracking of pots. This was due to excess of heat in one particular place on the pot, causing unequal expansion. A method of avoiding this was suggested.

BRITISH PHARMACEUTICAL CONFERENCE.

The fifty-eighth annual meeting of the British Pharmaceutical Conference was held at Scarborough from June 13 to June 16 inclusive, under the presidency of Major E. Saville Peck, of Cambridge.

In his presidential address Major Peck demonstrated the need for higher education. Pharmacy, if it is to progress, must move forward with the advance of general education and of applied science, and if it is to take up its position with other professions it must bring its final qualifications up to University and Continental standards. He advocated the institution of a fellowship examination which would entitle the holder to call himself a clinical analyst or clinical pharmacist, or registered clinical assistant of the Pharmaceutical Society, and urged the inclusion of practical physiological chemistry and bacteriology (including chemical microscopy) among the compulsory subjects. In British pharmacy to-day there is need of a closer union of purpose, counsel, and activity of all those who are working for a full realisation of the profession.

Among the papers communicated to the Science Section was one on "The Determination of Formaldehyde and Paraformaldehyde in Tablets," in which Messrs. Norman Evers and C. M. Caines described a method based on a comparison of the colour produced by the addition of Schiff's reagent to a solution of a tablet containing formaldehyde, with that produced by the same reagent on a standard solution of formaldehyde of known concentration. The accuracy of the estimation by the authors' method is not influenced by the presence of menthol, milk sugar, or cane sugar usually present in the tablets.

In a paper on "The Titration of Certain Alkaloids" Mr. Norman Evers showed that bromophenol blue is the most suitable indicator to use in the titration of morphine, atropine, and the neutral salts of quinine, but for an acid salt of quinine, methyl red is preferable. A method for the titration of ammoniated quinine for the combined determination of quinine and ammonia was described.

Mr. A. J. Jones read a paper on "The Quantitative Determination of Minute Quantities of Bromide in Saline Residues, and in a Mixture of the Halogens." The author advocates the use of a method which is a development of Denigès' process. The method is applicable when dealing with quantities of about 0·1 mg. of bromide existing alone or in admixture with iodide and chloride in water residues, or the residue from the ignition of any organic substance.

In a paper on "The Determination of Nitrates in Bismuth Salts by means of Titanous Chloride and Devarda's Alloy," Mr. T. McLachlan showed that the British Pharmacopœia method for the estimation of nitrates in bismuth carbonate is unreliable. The method for estimating the nitrate by reducing with titanous chloride, distilling with steam the ammonia formed, collecting in acid, and titrating back, was found tedious, but satisfactory results were obtained by using Devarda's alloy in alkaline solution in the presence of a small amount of alcohol. The author's method can be used for estimating the amount of nitrate in any bismuth salt excepting those in which ammonia is present.

In a paper on "The Determination of Small Quantities of Phosphate in Glycerophosphates," Mr. J. L. Lizius referred to the need on the biochemical side for a simple, rapid and accurate method for the estimation of small quantities of phosphoric acid, and on the analytical side to the need of a method for estimating small amounts of phosphate, present as impurities in glycerophosphates. The author's method is a tintometric one based upon a comparison of the colour obtained by adding nitric acid and ammonium molybdate to a standard solution of phosphoric acid and to a solution of the glycerophosphate under examination.

Mr. E. C. Davies communicated details of a process devised for "The Assay of Colchicum by means of Phosphotungstic Acid." Phosphotungstic acid precipitates colchicine in a bulky form in a 1·5 per cent. solution of sulphuric acid. The author's method may be summarised as follows:—The drug having been exhausted with alcohol, and the alcohol recovered, the colchicine is taken up with water, shaken out with chloroform, again taken up with hot water, precipitated as phosphotungstate, from which the colchicine is liberated either by chloroform and alcohol, or by chloroform, alkali and alcohol. The special advantages of the method described is that the alkaloid is obtained in a greater degree of purity than by other processes.

Messrs. C. E. Corfield and G. R. Boyes, in their paper "An Examination of Commercial Bismuth Phenate," showed that some samples of the salt contained little or no phenol. They suggested a method of preparation yielding a product containing 14·76 per cent. of phenol, this being the maximum content which it was found possible to obtain.

The following papers were also communicated to the meeting:—"The Ether-solubility of Scammony Resin"; "The Analysis of Theobromine Sodium Salicylate"; "A Note on Liquefied Carbolic Acid"; "The Quantitative Determination of Sodium Arsenate"; "The Assay of Atropine and Cocaine in the B.P. Ointments"; "The Approximate Estimation of Commercial Cresol in Lysol"; "A Contribution to the Study of Digitalis"; "A Note on the Official Method for the Determination of Hydrocyanic Acid"; "The Nature and Composition of Irish Moss Mucilage"; "The Action of Heat and Moisture on the Activity of Ergot and Liquid Extract of Ergot"; "An Investigation of some of the Factors which may determine the Keeping Qualities of Infundibular Extract"; "The Volumetric Determination of Arsenic Acid and Arsenates."

At the closing session of the Conference, Prof. H. G. Greenish, professor of pharmaceutics at the Pharmaceutical Society's School of Pharmacy, was elected president of the Conference for the ensuing year, and an invitation was accepted from the Nottingham Pharmaceutical Association to hold the annual meeting of the Conference at Nottingham in 1922.

PERSONALIA.

The University of Wales is to confer the honorary degree of Doctor of Science upon Sir J. J. Dobbie.

Dr. Eric K. Rideal has been appointed to the Humphrey Owen Jones lectureship in physical chemistry at Cambridge University.

Prof. S. P. L. Sörensen of the Carlsberg Laboratory, Copenhagen, has been awarded the Leblanc Medal of the Société Chimique de France.

The degree of Doctor of Science of the University of Manchester is to be conferred upon Messrs. F. W. Atack, Colin Campbell, and R. G. Fargher.

Dr. W. J. Jones, senior lecturer in chemistry in the University of Manchester, has been appointed to the chair of chemistry in University College, Cardiff.

Prof. J. von Braun, of Berlin, who was recently appointed director of the Chemical Institute in Frankfurt, has been called to the chair of chemistry in the University of Vienna.

Dr. C. F. Chandler, who was president of this Society in 1899—1900, and Dr. William H. Nichols, president in 1904—1905, have been elected honorary members of the American Chemical Society.

Dr. E. W. Washburn, head of the ceramic department of the University of Illinois, has been appointed editor of the *Journal of the American Ceramic Society* in succession to Mr. H. F. Staley.

The Nichols Medal, which is presented annually for the best original paper published in any of the journals of the American Chemical Society, has been awarded for 1920 to Dr. Gilbert N. Lewis for the paper on "The Third Law of Thermodynamics and the Entropy of Solutions and of Liquids," by himself and Mr. G. E. Gibson.

Dr. Robert Robinson has been appointed to succeed Prof. J. C. Irvine as professor of chemistry and director of the chemical research laboratory in the University of St. Andrews. Dr. Robinson was for several years professor of organic chemistry at Liverpool University and in 1920 was appointed director of research to the British Dyestuffs Corporation, Huddersfield.

We regret to record the death on June 21, at the age of eighty, of Mr. David Brown, late senior partner of J. F. Macfarlan and Co., manufacturing chemists, Edinburgh, and an original member of this Society.

The late Mr. William J. Chrystal, chemical manufacturer, of Shawfield Works, Rutherglen, and an original member of this Society, bequeathed £10,000 each to the University and the Royal Technical College, Glasgow.

The death is announced of Dr. F. P. Dewey, head chemist of the Mint Bureau, Treasury Dept., Washington, D.C., who joined this Society in 1889; also of Ambrose Monel, at the age of 47, the inventor of "Monel" metal. Monel was a graduate of Columbia University and became the first president of the International Nickel Co. in 1902, at the age of twenty-nine.

Dr. Ludwig Knorr, professor of chemistry in the University of Jena, who died on June 4 in his 62nd year, is perhaps best known for his discovery of antipyrin and for his researches in the pyrazole group, but his work on the constitution of morphine, on new methods of synthesising amino-alcohols, quinoline and pyrrole, and his investigations on keto-enol equilibrium will long be remembered as outstanding achievements in the sphere of organic chemistry.

NEWS AND NOTES.

UNITED STATES.

The Bureau of Mines Cryogenic Laboratory.—T new Cryogenic Laboratory of the U.S. Bureau Mines was opened by Madame Curie on the occasi of her recent visit to Washington. The main wo of the laboratory will be to obtain fundamen scientific data, especially such as will enable t Government plants to produce helium more e ciently and at lower cost. Its second and subsidia object is to provide facilities for a limited numl of American scientists who wish to carry out spec low-temperature investigations, particularly alo lines not covered by the work of the technical st of the Bureau of Mines. The laboratory is direc by Dr. R. B. Moore, chief chemist to the Bureau Mines.—(*Chem. and Met. Eng., May* 25, 1921.)

Sugar Consumption in 1920.—According to statist published in the *American Sugar Bulletin*, the c sumption of refined sugar in the United States 1920 was 4,075,173 tons, as against 4,126,673 in 1919, the *per capita* consumption in the t years being 86·35 and 87·45 lb., respectively. the total sugar consumed, the United States p duced 144,000 t. cane, 900,000 t. beet, and 20, t. of other sugars. A feature of the imports the large supply obtained from Java and ot countries that pay full tariff rates, rendered ne sary by the heavy consumption of home-produ sugar in the autumn of 1919 and the decrease the Cuban crop of 1919–20. There was a decr of 268,106 t. in the exports (roughly 400,000 so that a larger amount became available for h consumption. Stocks in hand on January 1, 1 were 1,093,545 t., the stocks of domestic cane beet, and imported sugar being 715,862 t. grea than in 1919. This stock is about equal to the crop of Cuban sugar still held in Cuba, an therefore by no means excessive (*cf.* J., 1921, 173 —(*Ind., Tr. J., May* 20, 1921.)

Cadmium in 1920.—Further progress is repo in the output of cadmium in the United Sta the production in 1920, 129,283 lb. of metal, val at $151,261, being nearly 30 per cent. greater t in 1919. The production of cadmium sulp amounted to 32,133 lb., valued at $37,133, against 31,197 lb. in 1919. Since 1910 the Ameri production has steadily increased, and Germ with a production of 85,395 lb. in 1919, now t second place. The metal has not been impo into the United States since 1915, but a 40,000 lb. was exported in 1918, chiefly to Fr (*cf.* J., 1920, 437 R). A comparatively new for cadmium is in making small-arms ammunit a cadmium band on the hard-jacketed cartr ball takes the rifling with little wear on the ba and thus prolongs the life of the gun. Ele plating with cadmium offers promise of expan and as the metal is a better rust-preventive nickel, it might replace nickel for this pur were there less difference in price. It is sugg that as cadmium tarnishes more readily nickel the latter metal might be deposited first coat of cadmium. A commercial proces electroplating iron and steel articles has developed by the Udylite Process Co., Kok Ind. The pigment industry offers a good pro *tive field for the consumption of cadmium pounds, chiefly cadmium yellows and "cadm lithopone."—(U.S. Geol. Surv., May 12, 1921.)*

Bromine Production in 1920.—*According to a p liminary report of the U.S. Geological Survey,* t output of bromine in 1920 was 518·1 long ton valued at $745,381, a decrease of 37 per cent. quantity and nearly 40 per cent. in value compare with 1919. The production, however, was great

than in any year prior to 1918 (*cf.* J., 1921, 173 R). The average price per lb. received by the producers rose from 13 cents. in 1910 to $1.31 in 1916 and was 64 cents. in 1920, which is more than three times the average price in 1913.—(*Official.*)

FRANCE.

Industrial Notes.—*Chemical Industry.*—Owing to the continuance of the trade depression, more factories are closing down, the latest being those of the Société Normande de Produits Chimiques. The situation, however, is held to be merely temporary, and preparations are being made for an economic revival. Thus the Compagnie Nationale de Matières Colorantes et de Produits Chimiques is organising the production of dyes at its factory at Villero-Saint-Paul, north of Creil. The factory covers an area of 111 acres, and is divided into three groups; the first has been producing indigo for some time; the second has just started to manufacture alizarin; and the third is preparing to produce indanthrene. It is anticipated that the output of these three products and their derivatives will not only cover home requirements, but leave a surplus for exportation; and it appears that an outlet has already been found in China. More than 75 chemists are employed and, apart from the existing works laboratories, a large central research laboratory is to be established this year. The company has allocated 250,000 francs for the furtherance of research in the chief technical universities. The Claude synthetic-ammonia process is likely to be established shortly in the Landes district of south-west France, where coal, electric-power, and salt are available. It is intended to produce ammonium chloride for fertilising purposes.

Metallurgy.—The export of ferrous scrap is now free and the 20 per cent. *ad valorem* duty has also been abolished. Stocks of iron ores are considerable, and in a few mining areas extraction has been stopped. Some producers still hold fairly large supplies of pig iron, but the stocks of others are entirely depleted. The price of hæmatite pig iron has been fixed at 450 fr. per metric ton as from June 1, which represents a reduction of 85 fr. on the price at April 1 last. Production of steel has been reduced and stocks, especially of heavy steel, do not find a ready market.

Coal.—Great activity prevails at the chief mining centres, as demand is reviving owing to depletion of stocks consequent on the continued export of coal to England. Thus the stocks of the East, State, and North railways are 50 per cent. lower than in April. The mines devastated during the war produced 392,045 t. in April or 27,750 t. more than in March.

Power and Transport.—The Senate has approved a scheme to utilise the Rhine for the production of 00,000 h.-p., for making it navigable over a distance of 500 km. and enabling irrigation to be applied to an area of 494,000 acres. The cost is estimated at 3000 million fr., and the annual revenue to accrue to the State at 300 million fr.

The railway system in Algeria is to be extended during the present year in order to open up the various mining areas that have been discovered in recent years; about 1539 million fr. will be spent on new construction and on repairing existing lines.

Clove Production in Madagascar.—Practically all the cloves exported from Madagascar are produced on the island of St. Marie, off the north-east coast, only some 10 to 15 metric tons being grown on the mainland. The exports, mainly directed to France, were 143 t. in 1918 and 499 t. in 1919; the 1920–21 crop amounted to only 20 t., although 87 t. was exported in December, 1920. The outlook for the 1921–22 crop is stated to be good.—(*U.S. Com. Rep., Apr. 23, May 7,* 1921.)

The Graphite Situation in Madagascar.—According to a statement published by the Madagascar Service of Mines, the production of graphite in Madagascar in 1920 was between 4000—5000 metric tons (1919, 4000—5000 t.; 1918, 16,000 t.; 1917, 35,000 t.). Exports during the year amounted to 14,919 t., of which 4449 t. went to England, 2127 t. to the United States, 51 t. to Belgium, and the remainder to France. Stocks at the end of the year were about 24,000—25,000 t., nine-tenths of which consisted of flake and one-tenth of amorphous carbon. Three-quarters of the flake graphite in stock averaged 80—90 per cent. carbon, the tendency now being to turn out a quality averaging 90 per cent. and above owing to the small demand. About 20 per cent. of the production is treated mechanically, some half-dozen plants being equipped with drying and separating machinery (*cf.* J., 1921, 110 R).—(*Bd. of Trade J., May* 26, 1921.)

SOUTH AFRICA.

Eucalyptus Bark as a Cork Substitute.—A correspondent writing in the *South African Journal of Industries* of March-April, 1921, draws attention to the value of the thick bark of the gum tree (*Eucalyptus sideroxylon*) as an insulating medium for refrigeration plants. A test carried out by Messrs. Sykes and Co., Ltd., of Johannesburg, showed that the insulating property of eucalyptus bark, when kept dry, was about equal to that of granulated cork, the actual figure obtained being 1·32 B.Th.U. per sq. ft. per degree difference in temperature per 24 hrs., using insulation 6 in. thick. As the bark is at present a waste product, the suggested new use should be worth consideration.

AUSTRALIA.

Industrial Notes.—The Hoskins Iron and Steel Co., Ltd., which owns large iron and steel works at Lithgow N.S.W., has purchased 380 acres of land at Port Kembla, near Wollongong, N.S.W., as a site for additional steel works. The estimated expenditure is approximately £2,000,000, and it is intended to purchase as much as possible of the plant and equipment in the United Kingdom.

Mr. A. Gibson, who is now exploring Papua (New Guinea), has applied to the Australian Government for a concession to exploit the nipa palm in the Fly River District. He guarantees a production of 500 tons of paper pulp per week and 3 million galls. of motor spirit per annum, and is reported to be willing to expend £300,000 on the erection of a plant and to employ 60 whites and 1500 natives.—(*Official.*)

JAPAN.

The Dye and Colour Industry.—The trade depression has affected the Japanese dye industry so adversely that at the beginning of this year only the larger and well-established factories remained in operation, and even these are now in a difficult position owing to growing German competition both abroad and at home. Nevertheless considerable progress has been made in the production of the chemicals required in dyemaking. Caustic soda and alkali of good quality are produced in fair amounts; acetic acid, acetone, nitric acid, ammonia, and glycerin are being made; nitrogen fixation and the production of soda ash have yet to be undertaken. The expectation of the *ad valorem* duty (35 per cent.) on all imported dyes was the cause of an abnormal increase in imports during 1920, so that the market became overstocked. The proposal to amalgamate the dye factories met with opposition and was not consummated. It is reported that the Japanese Government intends to stimulate dye-production by assisting the Japan Dye Manufacturing Co., which was floated at the beginning of the war. The progress made by the Japanese dye industry is

shown by the following statistics of imports in 1913 and 1919:—

	1913. lb.	1919. lb.
Indigo, natural	27,650	1,930,812
Indigo, synthetic	2,203,969	521,316
Logwood extract	963,624	1,846,605
Alizarin	212,661	—
Aniline	9,816,613	4,364,880
Coal-tar dyes, other	—	114,985
Ultramarine blue	324,980	183,960
Prussian blue	87,662	—
Cobalt oxide	40,489	114,414
Liquid gold, silver and platinum	59,897	2,133

Of a total import of 13,737,545 lb. of dyes in 1913, over 80 per cent. came from Germany, but in 1919, out of a total of 5,943,371 lb., the United States supplied 83 per cent.; in 1920, the origin of the 4,479,863 lb. of coal-tar dyes imported was as follows:—United States 67, Germany 17, United Kingdom 6, and Fance 4 per cent. During 1920 Japan exported 5,595,140 lb. of coal-tar dyes, but it is not known whether they were made in the country or transhipped (*cf.* J., 1921, 32 R).—(*U.S. Com. Rep., Apr.* 30, 1921.)

GENERAL.

A New Colour Index.—The last edition of "Farbstofftabellen" by Dr. Gustav Schultz, published in 1914, has become out of date owing to the great changes in the colour industry brought about by the war, and for some time past those interested in the production and application of dyes have felt the need of a new book dealing concisely with the constitution and properties of the whole range of colouring matters. The Council of the Society of Dyers and Colourists has, therefore, now decided to publish a Colour Index to supply this want, and Dr. F. M. Rowe has been appointed to edit it. In order to ensure accuracy and to include the maximum amount of available information, the Society of Dyers and Colourists has invited colour manufacturers throughout the world to co-operate in this publication by supplying the trade names, constitution, and properties of all known dyes of technical importance, and the proofs of the book will be checked by an expert revising committee representing every section of colour production and use. All references to patent and scientific literature will be brought up to date and checked in order to eliminate the errors which are to be found in previous reference books of this type. The Colour Index will be published in twelve parts, and every effort will be made to issue the first part within six months.

The Coal-tar Colour Industry in Italy.—When the manufacture of coal-tar colours in Italy was started in 1915, considerable difficulties were encountered owing to the lack of technical experience and the need for economising fuel and employing Italian raw materials as far as possible. Production commenced with the colours most in request and which could be manufactured most easily, viz., Sulphur, Azo, and triphenylmethane dyes. These three groups constitute roughly 60–70 per cent. of the Italian consumption, which prior to the war amounted to 6500 metric tons per annum (Sulphur dyes 1500 t., Azo dyes 3000 t.). The present output of 1300–1400 t. of Sulphur dyes and 2500 t. of Azo dyes is not so inadequate as has been affirmed. The criticism that fast cotton colours and vat dyes, like indigo and indanthrene, are not produced is held to be unwarranted, as the demand is too small. However, it has been announced that these colours are now to be manufactured by the Italica and Bonelli companies. At present the industry is passing through a crisis which, apart from the general trade situation, is accentuated by the total lack of protective duties and by the fact that German reparation colours (*cf.* J., 1920, 438R) are being sold in Italy at prices lower than those of similar goods imported privately from Germany. If such obstacles were removed the Italian dyestuff industry would make much greater progress.—(*Giorn. Chim. Ind. ed App., Apr.*, 1921.)

The Camphor Industry.—The Japanese camphor monopoly and the remarkable growth of celluloid manufacture in Japan, together with the correlated decrease in the exportable surplus of camphor, have stimulated the search for new sources of supply and for substitutes in the manufacture of celluloid. There is little chance of an increased supply from Japan as the hope of obtaining the product by distilling the leaves has been disappointed, and although the camphor from the young trees is said to be unsatisfactory, the maintenance of the Japanese output implies the cutting of trees less than 35 years old, whereas the highest yield is not obtained until the trees are 60 years old. American buyers are looking to China for new supplies, as there is an immense number of camphor trees in the Shan States of South-West Yunnan. In Fukien the remaining trees are more or less inaccessible, but experimental production from wild and planted trees is being carried out in the island of Hainan. A Chinese authority has suggested that a foreign syndicate should start operations in South Hainan and South Kiangsi, and extend them later to Kweichow, Kwangtung, and Kwangsi. In the United States, where camphor production began in 1904, the Celluloid Co. now has 3000 acres planted at Satsuma, the Arlington Co. 12,000 acres at Waller, and planting has also been carried out in Texas and in the San Joaquin Valley, California; the yield approximates 120 to 150 lb. of camphor per acre. As the Philippines offer prospects of successful cultivation, an American company has acquired there the control of a large area of suitable land. The camphor tree has been grown more or less successfully in Madagascar, the Canary Islands, Buenos Ayres, and Algeria, but it is to be feared that the true species *Cinnamomum camphora* is sometimes confused with the less camphoraceous *C. glanduliferum*. Within the British Empire, in addition to the Federated Malay States, Ceylon, and Mauritius, the species grows well in Burma, the Nilgiris, Dehra Dun, at Amani in Tanganyika, and in Queensland; experiments in South Africa suggest that the tree might be profitably cultivated in some of the warmer and moister parts of the Union. It is clear that the camphor tree can be grown successfully within the British Empire, and if care be taken to secure the true species, the small but constant yield of camphor obtained by distilling the leaves would be amply remunerative, even at prices below those now obtaining.

Hitherto synthetic camphor has been unable to compete with the natural product. The so-called "artificial camphor" differs widely from the true camphor and consists of pinene hydrochloride, prepared by treating turpentine oil with dry hydrogen chloride, but true synthetic camphor is made by oxidising borneol or isoborneol prepared from pinene hydrochloride or hydrobromide. The synthetic product closely resembles true camphor, but is usually optically inactive and often contains small amounts of borneol and other substances. As camphor can be manufactured in Formosa at an export price of 6d. per lb., this constitutes the limit to the cost of its production elsewhere. It is stated that 36 gallons of turpentine is required for 98 lb. of camphor, and this, with turpentine at 46s. per cwt., implies a cost of about 1s. 4d. per lb. of camphor for turpentine alone. Efforts should be made to obtain supplies within the British Empire by cultivating the tree in suitable areas and by manufacturing the synthetic product in the United Kingdom (*cf.* J., 1920, 76, 149, 185, 236, 306, 331, 379, 381 R, 1921, 148 R).—(*Imp. Inst. Bull. XVIII*, 4).

A New Process for the Cold Vulcanisation of Rubber.—G. Bruni has devised a new process for the cold vulcanisation of rubber which is based upon the formation in the nascent state of thiocarbanilide, or other substituted thio-ureas, within the mass of the rubber by the interaction of carbon bisulphide on aniline in presence of zinc oxide or other metallic oxides.—(*G. Chim. Ind. ed App., May*, 1921.)

Synthetic Nitrogenous Fertilisers in Germany.—The recent addition of 700 million marks to the capitalisation of the chief German dye companies (*cf.* J., 1921, 174 R) promises well for the future of the nitrogen-fixation industry, since all the associated firms have expressed their intention to allocate a considerable proportion of the new capital to the development of the nitrogen works. Prior to the war the annual production of nitrogen was about 100,000 metric tons, derived from gas and coke-oven installations; to-day these undertakings supply only a small proportion of the total output (gas works about 5 per cent.). In a recent review of the subject, Dr. Bueb, managing director of the Nitrogen Syndicate, stated that the annual production of cyanamide was limited to about 100,000 tons (fixed nitrogen), that the maximum annual output capacity of the synthetic ammonia plants was at present about 300,000 t., and that of the gas and coke-oven plants about 100,000 t.; total 500,000 t. of fixed nitrogen. The days of the use of Chile saltpetre in German agriculture are clearly numbered. Whereas in 1913, 770,000 t. was imported, the imports in 1920 were at the rate of only 40,000 t. per annum (Jan.—Oct. 31,284 t.). This reduced importation meant a clear saving to the German people of over 2000 million marks at the current rate of exchange. It is worthy of note that agriculturists have at last become convinced that sulphate of ammonia is the equal of Chilean nitrate in fertilising value. A good deal of ammonium nitrate is now being used, the difficulties due to its hygroscopic nature having been overcome; but the future seems to lie with synthetic urea, on account of its very high nitrogen content, its harmlessness when applied too heavily, and its good keeping qualities; large-scale experiments with it are now being conducted in Bavaria, and results should be available by the end of the year. Hopes are entertained that heavy dressings of nitrogenous fertilisers will help to revive the fallen sugar-beet industry and bring new life to the pastures. Prof. Neubauer, of Bonn, has shown the remarkable value of such heavy applications: within 4 weeks 65 per cent. of the nitrogen applied was converted into vegetable albumin, and if such results can be achieved on the large scale a pasture will be able to support twice as much livestock as hitherto. In order to promote intensive cultivation with nitrogenous fertilisers, the Nitrogen Syndicate has formed a subsidiary company with a capital of 500 million mk. to advance loans to consumers. Dr. Bueb is not in favour of utilising water-power in the nitrogen industry, except in a few of the cyanamide works, as the supply is small and far too fluctuating.

The Vegetable Oil Industry in Argentina.—The production of linseed oil in Argentina is sufficient to meet the requirements of domestic paint manufacturers and those in neighbouring countries, but the chief consuming countries usually prefer to import the seed for extraction in their own mills. Now, however, a Dutch company, the Cia. Sud Americana de Cereales, is erecting an oil mill near Rosario which, it is stated, will be the largest grinding plant in the world. Castor oil for industrial and medicinal use is produced in appreciable quantities, but rapeseed, colewort, and maize oils are only made in small amounts. The supply of cottonseed oil, which is produced on a small scale by most of the existing plants, will probably be augmented as a result of the increased acreage planted to cotton in the El Chaco territory; a new mill especially adapted for cottonseed-oil production is being built. Cottonseed and groundnut oils are both growing in importance as they are used as substitutes for imported edible oils. Olives have been grown experimentally in the province of La Rioja, but the extension of this crop is not likely to be very rapid. Vertical hydraulic presses are usually employed to express the oil, but extraction with benzine or trichlorethylene is used in a few plants; the mechanical equipment of the mills is said to be good.—(*U.S. Com. Rep., Mar.* 21, 1921.)

Cinchona Cultivation in the Philippine Islands.—According to the Director of the Philippine Bureau of Science, large areas in Luzon and Mindanao Islands are well adapted for cinchona cultivation, judging from the success obtained with a small plantation in Baguio under the supervision of the Bureau of Forestry. The climatic and general conditions in the Philippines are very similar to those in Java and India, where 90 per cent. and 10 per cent. respectively of the world's output are produced.—(*U.S. Com. Rep., May* 18, 1921.)

The Italian Mineral Industry.—Italy requires normally from 10 to 11 million tons of coal annually, but since the armistice only about 600,000 t. has been imported, largely owing to decreased supplies from Great Britain. Little can be expected from the coal deposits at Heraclea in Asia Minor (*cf.* J., 1920, 442 R), now under Italian control, not only on account of political unrest and lack of transport facilities, but because of the inferior quality of the coal. It appears that Italy will have to depend on imported fuel for some time to come, as the development of hydro-electric power on a large scale is impossible because of the great cost of erecting power stations and transmission lines. Italy produces a negligible amount of mineral oil, and the lignite is of poor quality, although it can be used to a limited extent when briquetted with powdered coal. Sufficient iron ore occurs in the island of Elba and at Cogne in the Val d'Aosta to supply the existing blast furnaces, but the production of pig iron by no means meets the demand; in 1919, 239,710 metric tons of pig iron was produced and 223,811 t. imported. An extension of electric smelting to other ores is feasible, and this would help to free the metallurgical industries from dependence upon imported fuel. Italy is a very important producer of mercury (*cf.* J., 1920, 204 R), especially since the accession of the Idrian mines; certain financial interests have considered the formation of a syndicate to sell the output of the Italian and Spanish mines, thereby ensuring control of the European market. For some time past the Italian sulphur industry has been declining from its former leading position, mainly through competition from the United States, labour difficulties, high costs of production, and inability to improve the output owing to the excessive subdivision of the mines into small holdings. Italy is still the leading producer of pumice, which is obtained chiefly from the volcanic island of Lipari, and nearly all of which is exported to the United States. A large proportion of the output of talc is exported, but of late both production and exports have fallen off. The output of zinc ore, which prior to the war exceeded 150,000 metric tons yearly and was nearly all exported, has fallen off by over 50 per cent. since 1914. Production of zinc metal is very small —1282 t. in 1919—and imports amount to less than 20,000 t. The output of lead ore has declined steadily from 44,654 t. in 1913 to 32,130 t. in 1919, and that of lead metal from 21,674 t. to 16,530 t. There are five producing copper mines, which in 1919 supplied 16,653 t. of ore, compared with 83,302 t. in 1918 and 89,487 t. in 1913; 1243 t. of

metal was produced and 79,425 t. imported. The following table shows that production of aluminium has been steadily increasing but is still insufficient to supply the entire home demand:—

	Production.	Imports.		Production.	Imports.
	Metric tons.			Metric tons.	
1913	874	483	1917	1,740	3,996
1914	937	312	1918	1,715	5,008
1915	904	1,665	1919	1,673	1,602
1916	1,126	2,132			

The demand for asphalt or asphalt products is not large and the home production, largely concentrated in Sicily, almost satisfies requirements.

Provisional figures for 1920 of the mineral production in Italy, including the new provinces of Trentino and Venezia Guilia, are as follows:—

	Metric tons.
Iron ore and ferro-manganese	423,300
Manganese ore	29,140
Copper ore	6,360
Lead ore	36,325
Zinc ore	98,090
Silver	500
Antimony	125
Iron and copper pyrites	322,450
Mercury	1,325
Fuel:—	
Lignite	1,662,430
Anthracite	28,600
Coal (triassic)	120.715
Bituminous shale	22 000
Shale (ichthyolitic)	495
Sulphur, raw and ground	293,000
Petroleum	4,750
Asphalt and bituminous rock	108,600
Bauxite	37,960
Graphite	4,190

—(*U.S. Com. Rep.*, *Mar.* 2, 14, 1921.)

LEGAL INTELLIGENCE.

Alleged Infringement of German Sulphur-Black Dye Patent. *A.-G. für Anilin Fabrikation in Berlin* v. *Levinstein, Ltd.*

With reference to the above case, of which a short report appeared in our last issue (p. 220 R), a correspondent writes that the decision that the use of sodium dinitrophenolate with sodium sulphide and sulphur is a different process from the use of dinitrophenol with sodium sulphide and sulphur will appear surprising to chemists, but the Court was obviously and, in his opinion, rightly impressed by the evidence that the plaintiffs—the patentees—in their own manufacture used sodium dinitrophenolate and kept it as "a factory secret of considerable importance." Two passages from the judgment are worthy of reproduction:—

"The plaintiffs themselves from the first manufactured their dye by using the sodium salt and not the dinitrophenol; the manufacture started soon after the date of the patent (1900), but when precisely does not appear. We regard this fact as one of very great importance. Dr. Liebmann, who was one of the principal witnesses for the plaintiffs, says that in 1913 he was for the first time told that the black dyes in question could be made from sodium dinitrophenolate, and that the plaintiffs were in fact making their dye in this way. (See evidence given in camera, page 67, question 2807 and following). He obviously regarded this as a matter of considerable importance, and as one which the plaintiffs would desire to keep to themselves."

Further:—

"We come the more readily to the conclusion that the plaintiffs and their advisers did not know that it was possible to obtain their dye by the substitution of the sodium dinitrophenolate for dinitrophenol because, if they did know it, it is difficult to understand why such possibility was not pointed out in the specification. We think it is clear on the evidence that for commercial purposes the substitution in question was economically an advantage and accordingly, by omitting to mention it, they were, on the assumption that they knew the facts, laying the patent open to attack on the ground that the patentees had not informed the public of the best way known to them of putting the invention in practice."

It is important to understand that this is not a decision that when the use of an acid is patented working with the salt is not an infringement. Another point of first-rate importance for chemical patentees is the distinction drawn by the Court between this case and the Half-Watt Lamp case, The British Thomson-Houston Co., Ltd., *v.* Corona Lamp Works, Ltd. (*cf.* J., 1918, 117 R).

"The remaining objection to the patent is that of insufficiency of description. Practically it resolves itself into this, that the patentees leave undefined the limits within which variation of proportions is permissible. The answer to this objection, we think, is this, that the proportions are not an essential part of the description. The patentee gives an example, by following which the result can be obtained. The possibility of varying the proportions without effecting the result is merely mentioned as one of the points in which the patented process differs from Cassella's. Under such circumstances we see no objection in point of law to a specification which, while giving a definite prescription, leaves the proportions which a particular operator may employ to his own discretion, informed possibly by actual experiment. The case here is not like that of the British Thomson-Houston Company, Ltd. *v.* Corona Lamp Works, Ltd. (Reports of Patent Cases, 37, p. 227), recently before this Court; there the larger diameter of the filament was of the essence of the invention and, this being so, it was held that the specification was insufficient because the patentee did not state what he regarded as a large diameter. For these reasons we agree with Mr. Justice Sargant that the objections to the validity of the patent fail."

This part of the judgment, our correspondent thinks, will make it a much-quoted case.

PARLIAMENTARY NEWS.

HOUSE OF COMMONS.

British Dyestuffs Corporation, Ltd.

Answering Sir W. Barton, Sir R. Horne said that the Government holding in the British Dyestuffs Corporation consisted of 850,000 £1 preferred ordinary and 850,000 £1 preferred shares, both fully paid; at current market quotations, these shares would be worth about £580,000, but in view of the present trade depression this figure afforded no adequate indication of the ultimate value of the investment. Recent changes in organisation indicated that whilst substantial progress had been made, the board was not entirely satisfied with the position. The Government directors were in full accord with their colleagues as to the necessity of taking every possible measure to secure greater efficiency in the conduct of the undertaking, and steps had been taken to that end.—(June 9.)

Lead Paints.

Mr. Hannon asked if the recent experience of the Office of Works had shown that leadless paints were neither as economical in use nor as durable as lead paints, and whether any report had been prepared by H.M. Office of Works on the relative economic value of lead paints and leadless paints. In reply, Lieut.-Col. Sir J. Gilmour stated that

the experience of the Office of Works with leadless paints was being carefully reviewed for the information of the Home Office and in connexion with the general question of the prohibition of the use of lead paints which was to be discussed at the International Labour Conference in October.—(June 13.)

Dyestuffs Development Committee.

Capt. Elliott asked the President of the Board of Trade whether an application had been received from the British Association of Chemists, as representing technical chemists engaged in the industries making and using dyestuffs, for representation on the Development Committee to be set up under the Dyestuffs (Import) Regulation Act, 1920. In reply, Mr. Baldwin said that the application had been received, and although the object was to secure a fully representative committee this did not imply the appointment of a representative of each individual association. Satisfactory progress had been made in the constitution of the committee and an announcement would be made at an early date.—(June 20.)

Imports from European Countries.

Replying to Capt. Coote, Mr. Baldwin stated that the imports of pig iron and steel from Europe into the United Kingdom during 1920 were valued at £11,853,528 and included;—Pig iron, 177,202 tons; ingots, not special steel, 7427 t.; blooms, billets, slabs, steel, not special steel, 54,480 t.; special steels, 310 t.; the total imports of all descriptions of iron and steel and manufactures thereof were 467,432 t., worth £11,853,528; and the total value of all imports, except food and drink, into the United Kingdom from Germany was £28,319,000.

In an answer to Sir W. Barton, Sir P. Lloyd-Greame said the imports from Germany during the period January—March, 1921, included the following items:—Finished coal-tar dyes, other than alizarin and synthetic indigo, £472,104; crude zinc, £338,925; wire, other than uninsulated electric and fencing wire, £156,278; machines and machinery, not specified, £129,588.—(June 20, 21.)

The British Cellulose Co.

Lord H. Cavendish-Bentinck asked the Chancellor of the Exchequer whether he was aware that the British Cellulose Co. had stated in its prospectus that the company's plant was capable of turning out a large quantity of artificial silk, although at the time of issue of the prospectus the promoters of the company had not discovered the process of making an artificial silk which would dye; and if the Government was responsible for the issue of this prospectus. In reply, Mr. Young said that the Chancellor of the Exchequer was advised that the silk produced by the company had always been capable of taking dyes The Government was not responsible for the issue of the prospectus, but merely approved the reference in it to the Government's acceptance of preference shares.—(June 21.)

H.M. Factory Gretna.

Sir L. Worthington-Evans, in reply to Major W. Murray, stated that the Government had decided to dispose of the factory at Gretna.—(June 21.)

Duty on Spirits.

Mr. Young, replying to Major Kelley, said that an amendment was moved to the Finance Bill last year to the effect that spirits used in the manufacture of perfumes and similar substances should be treated similarly to spirits used in medicinal preparations or for scientific purposes. The amendment was withdrawn and he saw no reason to modify the decision then taken.—(June 21.)

REPORTS.

Mines and Quarries: General Report, with Statistics, 1920. *By the* Chief Inspector of Mines. Pt. I.—Divisional Statistics. *Pp.* 27. *London: H.M. Stationery Office.* 1921. *Price* 3*d.*

The number of mines operated in 1920 was 2851 under the Coal Mines Act, and 498 under the Metalliferous Mines Act, compared with 2843 and 495, respectively, in the previous year. In addition, there were 5479 quarries at work (5135 in 1919), making a grand total of 8828 mines and quarries, or 355 more than in 1919. The total number of workers employed in or at the mines and quarries was 1,337,297, of which 93·3 per cent. was employed under the Coal Mines Act, compared with 1,270,050 and 93·8 per cent. in the preceding twelve months. There were 1184 deaths from accidents, and the accident death-rate under the Coal Mines Act was 0·88 per 1000, as against 1229 and 0·94 per thousand in 1919. The appended table summarises the output of minerals from all sources in the United Kingdom during 1920:—

Summary of output of minerals from mines, quarries and brine wells.

	Tons. 1919.	Tons. 1920.
Alum shale	5,539	4,848
Arsenic	1,997	2,527
Arsenical pyrites	1,178	75
Barium compounds	64,150	60,087
Bauxite	11,020	9,221
Bog ore	2,179	3,045
Chalk	3,747,165	2,629,406
Chert, flint, &c.	84,303	50,082
Chromite of iron	1,100	150
Clays* and shale	11,030,418	7,765,965
Coal	229,532,081	229,779,517
Copper ore and copper precipitate	275	372
Fluor spar	54,683	36,860
Gold ore	1	—
Gravel and sand	2,757,052	2,048,427
Gypsum	286,978	220,003
Igneous rocks	5,620,691	4,387,703
Iron ore	12,707,475	12,254,195
Iron pyrites	6,659	7,336
Lead ore	15,399	13,868
Lignite	150	—
Limestone (other than chalk)	11,227,817	9,537,495
Manganese ore	12,875	12,078
Natural gas (cb. ft.)	(95,000)	(90,000)
Ochre, umber, &c.	14,957	10,547
Oil shale	2,842,582	2,763,875
Rock salt	108,083	90,938
Salt from brine	2,050,287	1,817,142
Sandstone	2,183,816	1,699,853
Slate	215,269	164,098
Soapstone	361	688
Sulphate of strontia	4,183	1,872
Tin ore (dressed)	4,858	5,156
Tungsten ores	94	166
Uranium ore	60	—
Zinc ore	5,064	6,933
Total	284,600,799	275,384,528

* Including china clay, china stone and mica clay.

Report on the Commercial and Industrial Situation of Sweden at the end of 1920. *By* H. Kershaw, *Commercial Secretary to H.M. Legation, Stockholm. Pp.* 40. *Department of Overseas Trade. London: H.M. Stationery Office.* 1921. *Price* 1*s.*

Among the many difficulties with which Swedish industries had to contend during 1920 were severe competition from Germany, high cost of production partly due to the high price of coal, high wages, the 48-hour week, and strikes. Increased protection was solicited by the iron and steel, glass, and certain other industries, but the Government authorities decided against any general rise in customs duties and import prohibitions, although these were recommended for adoption in certain isolated cases. The timber industry was prosperous, and the year

was a very profitable one for paper and pulp manufacturers, the exports comprising 585,000 tons, dry weight, of bleached and unbleached sulphite pulp (561,325 t. in 1919); 141,000 t. of bleached and unbleached sulphate pulp (119,074 t.); and 281,965 t. of mechanical pulp, wet and dry (207,712 t.). By the end of the year large stocks had accumulated, the European demand had fallen off but that from the United States had increased, and generally, prospects were uncertain. Output in the iron and steel industry was considerably below the average of the previous ten years owing, it is suggested, to labour troubles, but the export trade was good. At the date of the report the industry was in a difficult position and clamouring for protection. Exports of iron ore amounted to 3,736,000 metric tons, compared with 2,419,000 t. in 1919 and 6,440,000 t. in 1913 (a record year). The Lapland ore, unlike the ore in Central Sweden, is high in phosphorus, but the supply is practically inexhaustible; it is exported chiefly to Germany. Conditions in the chemical industry were fairly good until the summer, and then became steadily worse; glass manufacture is being hit by Belgian competition, but production in the match industry is gradually returning to the pre-war level. A law has been passed prohibiting the use of yellow phosphorus in the manufacture of matches. The high price of coal has led to serious consideration of the country's water-power resources, the estimated supply of water power during about nine months in the year being 6,750,000 h.-p. The total production of electric energy at the State power-stations in 1920 was 740 million kw.-hrs., compared with 685 millions in 1919. Rapid progress has been made in the electrochemical industry, which now exports considerable quantities of calcium carbide, nitrolim, chlorates, perchlorates, sodium sulphate, chloride of lime, and electrometallurgical products such as iron and steel, ferrosilicon, ferromanganese, zinc and lead.

The import and export returns for 1920 include the following items:—

Imports.

	1920. Metric tons.		Inc. or dec. over 1919. Per cent.
Sugar, all kinds	60,425	..	+540·3
Hides and skins, undressed	11,912	..	− 1·7
Mineral oils	189,730	..	+ 16·7
Coal tar	11,367	..	+ 18·5
Vegetable oils and fats	17,690	..	− 57·4
Linseed	27,555	..	+ 56·1
Oilcake	64,356	..	− 6·2
Vegetable tanning materials, extracts	3,589	..	− 72·3
Zinc white, lithopone, barytes (white)	5,311	..	+102·7
Salt, domestic	26,843	..	+ 87·4
Sodium sulphate and bisulphate	50,337	..	+273·6
Soda and sodium bicarbonate	18,783	..	+ 32·1
Chile saltpetre	23,048,584	..	− 0·7
Calcium nitrate	22,302	..	+301·3
Phosphates, crude	112,853	..	+ 62·8
Stassfurt salts	49,508	..	− 60·4
Pyrites	114,600	..	+ 60·7
Coal	2,806,303	..	+ 45·5
Coke	358,259	..	+ 28·4
Briquettes	16,973	..	+ 2·5
Iron and steel	212,878	..	+ 71·3
Copper, crude	18,178	..	+ 24·2

Exports.

Pulp, wood:—			
Mechanical, wet	214,210	..	+ 34·9
Mechanical, dry	57,755	..	+ 14·0
Sulphite cellulose, bleached	44,162	..	+ 54·1
Sulphite cellulose, unbleached, wet	40,733	..	+ 61·1
Sulphite cellulose, unbleached, dry	511,859	..	− 1·9
Sulphate cellulose	140,548	..	+ 18·0
Cardboard, paper, etc.	284,999	..	+ 15·7
Cement	68,131	..	+ 83·2
Superphosphates	42,376	..	+279·7
Matches, wooden	36,450	..	+ 28·2
Iron and steel (includ. manufactures)	222,678	..	+ 8·7

The writer of the report draws attention to the great loss incurred by British manufacturers in carrying on their Swedish business through agencies established in other Scandinavian countries.

COMPANY NEWS.

BRUNNER, MOND AND CO., LTD.

In his speech to the annual general meeting, held at Liverpool on June 15, Mr. Roscoe Brunner (chairman of directors) said that the new company—Synthetic Ammonia and Nitrates, Ltd.—had erected at the works of Castner Kellner a semi-large scale plant of the Haber type, but with improvements, and this had been running for some weeks producing about 1 ton of ammonia per day, soon to be increased to 2 tons. The plant, which was the most complicated the company had erected, was designed and started with exceptionally few troubles, and the experience gained would render much easier the designing and operating of the large plant to be erected at Billingham. The technical results obtained confirmed the expectation that with any reasonable cost of construction and any probable selling price, the business would be a profitable one.

Referring to the present industrial depression, Mr. Roscoe Brunner said that trade had suffered the severest slump it had ever known and that recovery must necessarily be slow. The wealth destroyed in the war could only be replaced by hard work and saving, and to save the people must be able to buy in greater quantities at a lesser cost. Costs must be reduced by lowering wages, since in the cost of production of every article wages is by far the largest item, averaging at least 70 per cent. The reductions in wages had not gone nearly far enough. Salaries, too, must be reduced, and the Government must lead the way in economising; every Government service which is not of vital necessity must be scrapped. When the new capital was issued in April, it was intended to continue the erection of the Wallerscote Works and the Synthetic Ammonia Works at Billingham, but owing to the incidence of the coal strike and the uncertainty of the immediate future, the company's building programme had been postponed in its entirety.

The gross trading profit for the year ended March 31 last was £493,165, after deducting depreciation, compared with £826,000 in the previous year, but investment revenue increased from £460,000 to £655,479, and the net profit was £936,000, as against £1,126,000. The decrease in the total dividend on the ordinary shares from 11¼ to 8 per cent. is partly due to the increased capitalisation and partly to the severe depression which set in last November.

ZINC CORPORATION, LTD.

The annual general meeting, held in London on June 15, was addressed by Mr. F. A. Govett, chairman and managing director.

With present working costs, working hours, and metal prices, the company's mine cannot be worked at a profit, and operations are now confined to producing zinc concentrates from the accumulated tailings (664,633 t.) and middlings (28,862 t.), of which the supply should last about 2¼ years, and from which the profit at current prices would cover the dividend on the preference shares. No development work is being done and the ore reserves at the close of the year 1920, exclusive of the zinc lode, were estimated at 2,115,700 tons of ore, averaging 14·6 per cent. lead, 2·6 oz. silver, and 9·4 per cent. zinc. The company has subscribed a further £50,000 to the Electrolytic Zinc Co., has invested £15,000 in a combine called the British-Australian Lead Manufacturers, to make subsidiary lead products, and has acquired an interest in another combine—the Broken Hill Globe Timber Co.—to ensure a supply of timber. The prosperity of the

company, said Mr. Govett, depends upon the cost of producing lead and zinc concentrates, and the price of lead and spelter; the former is practically entirely a question of the cost of labour, and the latter mainly one of the world's consumption and demand, which depend upon price and hence upon cost of production, *i.e.*, labour. The cost of labour is thus the vital factor throughout. For 19 months the company's mine at Broken Hill was closed down owing to a strike of labour, and when work was resumed in November on the terms of an award, it was found that those terms made profitable mining impossible, except with lead at an abnormally high price. If the 35-hour week prescribed by the award were abandoned for the 44-hour week, mining could be profitably carried on with lead at a considerably lower price.

The profit for the year ended December 31, 1920, was £34,409, out of which the preference dividend was paid for the first half-year (10 per cent.), but owing to the uncertain outlook no distribution has been made for the second half-year.

TRADE NOTES.

BRITISH.

Nigeria in 1919.—The year 1919 was marked by a revival in trade owing to the demand for oil-bearing materials, particularly palm oil, palm kernels, and groundnuts. Trade, however, was hampered by the inability of the railway to deal with all the produce. Cotton is quickly regaining its pre-war importance and the cocoa industry is developing steadily, the export in 1919, 25,511 tons, being five times greater than in 1914. Cultivation of rubber and of kola are being encouraged. In the Northern Provinces 88 tin-mining companies worked throughout the year and produced 8168 t. of tin ore (8434 t. in 1918). Gold mining was continued near Minna, in the Nupe Province, and 319 oz. of alluvial gold was won. The output of coal was 137,844 t. compared with 148,214 t. in 1918, the reduction being due to labour difficulties.

The total value of the imports during 1919, exclusive of specie, was £10,798,671, as against £7,423,158 in 1918. The British Empire supplied over 96 per cent. of the total imports, which included:—Kola nuts, 162,701 centals; salt, 54,755 tons; kerosene, 2,069,353 galls.; iron, steel, and manufactures of, 9972 t.; soap, 3016 t. Exports were valued at £14,675,789, exclusive of specie (£9,511,971 in 1918); they included:—Benneseed, 57,074 t.; rubber, 892,081 lb.; shea products, 1729 t.; tin ore, 7685 t.; palm oil 00,967 t.; palm kernels, 216,913 t.; groundnuts, 39,334 t.; hides and skins, £1,262,140. Eighty-five per cent. of the exports was directed to the British Empire, but both import trade and export trade with the United States have increased.—(*Col. Rep.-Ann.*, *No.* 1064, *Mar.*, 1921.)

FOREIGN.

Foreign Company News.—*Czechoslovakia.*—The following companies have recently been formed for the manufacture of artificial silk:—Gebrüder Kaader, Mahrisch-Ostrau, capital 20 million mk., with a daily output capacity of 1000 kg.; Elberfelder Glanzstoff-fabriken, Aussig, capital 50 million mk.; Th. Liebig, Reichenberg, capital 20 million mk.; Wolf and Schleim, Jos and Löwenstein and the Zivno Bank, Theresienthal near Arnau, capital 0 million mk.—(*Chem. Ind.*, *May* 30, 1921.)

France.—The Etablissements Kuhlmann is paying dividend of 12 per cent., the same as last year; the carry forward is 992,496 fr.

The Société d'Electro-Chimie et d'Electro-Métallurgie announces a net profit of 3,709,493 fr., and a dividend of 45 fr.

A net profit of 17,323,657 fr. was made by the Société Saint-Gobain in 1920; 7 million fr. was carried to reserve and the dividend payable is 245 fr. per share (210 fr. for 1919).—(*Rev. Prod. Chim.*, *June* 15, 1921.)

Germany.—Kalle and Co., A.-G., Biebrich, made a net profit of 3,030,000 mk. in 1920 and is paying 20 per cent. The dyestuffs produced by the company fetched good prices and the pharmaceutical section developed satisfactorily, but during the second half of the year sales decreased owing to foreign competition and the industrial crisis.

The net profit of the Vereinigte Kunstseidefabriken, A.-G., Frankfurt, for 1920 was 270,426 mk., the dividend is 9 per cent., and the capital is being raised to 8 million mk. The manufacture of staple fibre was found to be unremunerative and that of artificial silk was resumed in the middle of the year.

A dividend of 25 per cent., plus a bonus of 500 mk., making a total of 75 per cent., is to be distributed by the A.-G. für Chemische Industrie, Gelsenkirchen; 1,140,000 mk. was written off and 2 million mk. carried to maintenance account, leaving a net profit of 5,800,000 mk.

The turnover of the Chemische Fabrik auf Aktien vorm. E. Schering, Berlin, increased considerably, but early in the year production did not meet demand owing to lack of fuel and other difficulties. The net profit was 3,592,381 mk. and the total dividend 25 per cent.; the capital is to be raised to 11 million mk. to extend and modernise the works at Eberswalde.

The output of the Chemische Fabriken vorm. Weiler-ter-Meer, Uerdingen, in 1920 was less than one-half of the pre-war average, but owing to good prices in the first months the results for the year were favourable. Wages and salaries rose from 5,560,000 mk. in 1919 to 18,100,000 mk. in 1920, the number of employees remaining about the same. The balance to the credit of profit and loss was 7,133,367 mk. and dividends amounting to 18·5 per cent. have been paid or are payable.

Other dividend announcements are as follows:—Köln Rottweil A.-G., 16 per cent. (capital 66 mill. mk., to be raised to 100 mill. mk.); Dynamit A.-G. vorm. Alfred Nobel and Co., 16 per cent. (capital 72 mill. mk., to be raised to 100 mill. mk.); Rheinische-Westfälische Sprengstoff A.-G., 12·8 per cent. (capital 26 mill. mk., to be raised to 40 mill. mk.); Siegener Dynamit Fabrik, 12·8 per cent. (capital 1·2 mill. mk., to be raised to 1·8 mill. mk.). The Farbenfabriken vorm. F. Bayer and Co., Leverkusen, is paying 20 per cent. for the year and the capital is to be raised to 430 million mk.—(*Chem. Ind.*, *May* 23, 30, 1921.)

Poland.—A new company, the Polish Oil Co. "Polpetrol" has been formed with a capital of 60 million Polish marks. With the help of British and French capital it has acquired 490 acres of oilfields in the Sanok district, where eight wells have been sunk, and is about to purchase an additional 1162 acres upon which six shafts will be constructed during this year. The "Galician Joint-stock Oil Industry Co." is another new oil company, with a subscribed capital of 16,250,000 mk (Polish mk.=1s. at par, now about 0·04d.).—(*U.S. Com. Rep.*, *Apr.* 15, 1921.)

Spain.—The Industrial Resinera Ruth company has been formed by a German firm and the Sociedad Union Resinera Española, the latter subscribing 70 per cent. of the capital. The company will manufacture enamels, varnishes, paints, glue, aniline, and other chemical products, including synthetic camphor.—(*U.S. Com. Rep.*, *Apr.* 15, 1921.)

Yugoslavia.—The Kastel Factory of Chemical and Pharmaceutical Products, recently founded at Karlovatz, Croatia, will be the first company in the Balkans to manufacture medicinal products such as compressed tablets, serums, and medicinal plant products. The company will cultivate medicinal plants on a large property adjacent to the railway between Karlovatz and Ljubljana (Laibach).—(*U.S. Com. Rep., Apr.* 13, 1921.)

OFFICIAL TRADE INTELLIGENCE.

(*From the Board of Trade Journal for June* 9 *and* 16.)

OPENINGS FOR BRITISH TRADE.

The following inquiries have been received at the Department of Overseas Trade (Development and Intelligence), 35, Old Queen Street, London, S.W.1, from firms, agents, or individuals who desire to represent U.K. manufacturers or exporters of the goods specified. British firms may obtain the names and addresses of the persons or firms referred to by applying to the Department and quoting the specific reference number.

Locality of firm or agent.	Materials.	Reference number.
Bermuda	China, glassware	716
British West Indies	Soap, perfumery	717
”	China, glassware	718
South Africa ..	Crockery, glassware	705
”	Crockery, glassware, bottles, sheet glass, plate glass	707
Hungary	Raw materials for medicines, vegetable fibres, cork	729
Italy	Malt	711
Sweden	Leather belting	733
”	Chemicals for pulp, paper and other industries	734
Morocco	Galvanised sheets, electric light bulbs (120 volts)	713
Argentina ..	Heavy and fine chemicals ..	714

TARIFF. CUSTOMS. EXCISE.

Czechoslovakia.—The “Manipulation” fees on exports affect cardboard, chemicals (except hydrochloric acid), chloroform, cellulose pulp, collodion, cyanide, dyes, faïence, glass, gold, kaolin, artificial leather, matches, mineral wax, paper, photographic goods (except films), polish, platinum, porcelain, rubber goods, silver, tar and derivatives thereof, yeast, etc. Such fees are payable on imported hops leather, photographic films and papers, stoneware, and tannin.

France.—Extracted fats (wool grease, etc.) may now be exported without special authorisation.

The export duties on edible and other oilcakes have been abolished. The export of raw cattle bones is permitted subject to a duty of 3 fr. per 100 kg. The export of natural phosphate of lime is allowed until further notice to all destinations.

Germany.—Albumin may be exported without licence as from May 28.

Germany (Occupied Territory).—Import licences are not required for fats, hides, and iron ore, nor export licences for bricks and certain leather goods.

Greece.—A copy of the decree controlling the trade in opium, morphine, cocaine, heroin and preparations thereof may be seen at the Department, 18, Queen Anne's Gate, S.W. 1.

The import of sodium carbonate is again allowed.

Hungary.—For the purpose of the payment of customs surcharge, goods are divided into three classes. Goods in list A include cardboard, newsprint paper, and certain chemicals, and are surcharged 1100 per cent. List B, on which the surcharge is 1900 per cent., includes paper, fine cardboard, rubber, tanned skins, glassware, pottery, firebricks, crucibles, and certain chemicals. Goods in list C are surcharged 3400 per cent. Full particulars may be obtained on application to the Department.

Italy.—As from April 1 the payment of customs duties on a gold basis has been resumed. Payments may be made by certificates to be obtained from the Banks of issue at a price fixed fortnightly by the Minister of the Treasury.

The import of dyes and intermediates is prohibited, but certain exceptions may be specified from time to time by the Minister of Finance.

Japan.—The new tariff amendments came into force on June 1.

Nigeria.—As from June 1, in order to import morphine, cocaine, ecgonine, diamorphine, and medicinal opium the importer must furnish the Government with a statement in quadruplicate of his requirements and a guarantee that the consignment is required for legitimate scientific and medicinal purposes; the name of the firms supplying the drugs should also be stated.

Nyasaland.—The customs tariff has been revised with effect from April 1. All goods (with some exceptions) pay an import duty of 10 per cent. *ad valorem.* Among the articles that are duty-free are manures, disinfectants, insecticides, and drugs of the British Pharmacopœia.

Export duties are payable on gold and beeswax.

Poland.—The import of vinegar is prohibited. Zinc may be exported without licence as from April 16.

Portugal.—Export licences are required for, *inter alia*, butter, lard, olive oil, and sugar.

Goods on which export surtaxes are payable include lard, butter, matches, scrap iron, rosin, certain hides and skins, wolfram ore, and tin.

Rumania.—The export taxes on certain petroleum products have been modified.

Commission charges are levied on the export of certain seeds, sunflower oil, oilcakes, timber, carbide, carbon bisulphide, bleaching powder, gypsum, soap, salt, bitumen, grease, tar, pitch, petroleum products, lard, cement, tarred paper, old iron, manganese iron, oak bark, and shoemakers's glue.

San Salvador.—The import duty on gasoline has been reduced to 1½ centavos (gold) per kg.

St. Vincent.—A copy of the regulations relating to certificates of origin under the British preferential tariff may be seen at the Department.

Spain.—Modifications of the new provisional customs tariff affect coal-tar colours, aniline oil and hydrochloride, and pulp for paper making.

Surtaxes have been levied on all classes of goods.

Within the 8 months ending February 3, 1922, 25,000 metric tons of sugar may be exported.

Sweden.—Export prohibitions have been withdrawn from vegetable fibres, premier jus, oleomargarine, malt, starch, flax seed, rape seed, liquorice, and sweetened condensed milk.

Increased import duties are payable on hops, liquorice, cumin, certain spices, vanilla, saffron, incandescent mantles, and wares of gold, silver, and platinum.

Switzerland.—Import licences are no longer required for paper, cardboard, bottles, and certain manufactures of iron, copper, and of copper alloys when imported over the Franco-Swiss or Italo-Swiss frontiers.

Tunis.—The prohibition of the import of paper on reels and pulp for newsprint paper has been abolished.

Venezuela.—The regulations affecting the import, manufacture, and sale of foodstuffs may be seen at the Department.

REVIEWS.

FAMOUS CHEMISTS: THE MEN AND THEIR WORK. *By* SIR WILLIAM TILDEN. *Pp.* 296. (*London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co.* 1921.) *Price* 12*s.* 6*d. net.*

Sir William Tilden has written a book which will be not only a very convenient book of reference for chemists, but will appeal to general readers who desire to learn the main characteristics and achievements of some of the great men—from Boyle to Ramsay—who have built up the science of chemistry.

The question at once arises—who shall be included in such a book? As a guide to selection the author has taken the evolution of the atomic theory, -nd has chosen the men who, in his judgment, have ken the leading part in establishing, step by step, ie idea of the chemical element and the quantitave laws of chemical combination, the men who ave isolated new elements and those who have plained the structure of molecules from a study the properties of atoms. If twenty-one names ad to be selected from those whose work appeared dispensable to the progress of the theory, chemists ould not differ greatly from the author in their oice. In making an independent selection the riter was surprised to find how many of the same ames were included; indeed, in the case of the lder chemists, he can congratulate himself in "spotting" eleven out of the first twelve. This concordnce no doubt is due to the perspective of time: hen details are lost the great realities can be seen.

For all the chemists he has chosen Sir William ilden has given good reason why he has selected hem as "indispensables," and why their fame hould be preserved; and if we have a doubt in any articular case and think, for instance, that Proust vould hardly have persuaded the world that Berthollet was wrong in questioning the universalty of "definite proportions," had it not been for Dalton's atomic theory and the law of multiple roportions which Proust himself failed to see—vell, we all admit that Proust did brave work and re glad to have the details of his life. Among nodern atomic chemists we welcome the inclusion of Alexander Williamson as one of the great upholders of the theory, the inventor of the water-type and the first chemist to introduce the idea of intermolecular exchange, which lies at the root of the modern doctrine of ionisation.

If, where there is so much to praise, it is the critic's business to seek a point or two to debate, one point shall be on a matter of judgment, the other on a small matter of fact. In Dalton's life no mention is made of his experimental determination of the law that all gases under the same conditions expand alike for equal increments of temperature. Under Gay Lussac we find this reference:—". . . . like Dalton, he also adopted the erroneous idea that the expansibility of all gases was the same." Now Dalton, working with oxygen, hydrogen, nitric oxide and carbon dioxide, found that the actual expansion became less as the temperature rose, but all the gases behaved alike, and it is the equality of expansion of the different gases which he lays stress upon. Surely this generalisation which all continental writers ascribe to Gay Lussac, and was first enunciated by Dalton, had an important influence on the development of the atomic theory—in spite of the fact that neither experimenter determined the true coefficient of expansion. As to the matter of fact—a small fact admittedly—is Sir Wiliam Tilden (in company with most other chemists) justified in questioning the authenticity of "the pear-shaped vessel commonly called Cavendish's Eudiometer"? The writer has in his possession a glass "pear-shaped vessel" made by Newman; it was given to him 40 years ago by the Rev. T. H. T. Hopkins, Fellow of Magdalen, with this history:—It was made originally by Newman for Cavendish, and was brought back by Newman after Cavendish's death; it was purchased from Newman as Cavendish's instrument by Professor Daubeny, of Oxford, who left it to his friend Hopkins. The "Eudiometer" is a very thick-walled explosion vessel, the platinum firing-wires being fastened by cement in holes bored through the glass-stopper, which is clamped down just as shown in the Cavendish Society's plate.

Every chemist will find some new facts in this book, and will be pleased to see the old facts so skilfully arranged. Sir William Tilden has made excellent use of his materials, and every picture leaves a brilliant impression on the mind: he brings out the environment in which his heroes worked, and the stimulus they gave to their contemporaries. The word "heroes" is used designedly; for the author, if he errs at all, errs by way of admiration, and, only touching lightly on the controversial, rightly sets forth the good that is to be remembered.

HAROLD B. DIXON.

LES VERNIS. *By* CH. COFFIGNIER. *Preface by* M. HALLER. *Encyclopédie de Chimie Industrielle. Pp.* xviii.+640. (*Paris: J. B. Ballière et Fils.* 1921.) *Price* 40 *francs.*

Coffignier's book forms a welcome addition to the literature of the varnish industry. It opens with a very full and valuable account of the various gum resins, giving their origin, properties, chemical composition, and where possible tests for their recognition. The oil-resins, balsams, and also the artificial aldehyde-condensation-products, such as Baekelite, now being introduced as substitutes, are described. Asphalt and colouring matters, such as turmeric, aloes, and coal-tar colours follow. The analysis of gums is then given, including the acid and saponification values, which serve as useful guides. The iodine number, which the author rightly carries out with Hubl's solution, and not by Wijs or Hanus, as the gums are more soluble in alcohol than in acetic acid, proves of great value in determining the class of gum; but scant attention is paid to the action of air on the gum resins, as in the weathering of gums.

In the chapters on oils, linseed oil is first treated fairly well, but too little attention is paid to the constants of different varieties, such as iodine values. The same criticism applies to the other oils, such as tung, lumbang, soya, and some of the lesser known oils which are mentioned. This fault, however, is almost remedied in a later chapter on the analysis of oils. Apropos of the iodine value, the author still gives the view that the iodine is absorbed from the various solutions in the form of hypoiodous acid, which was disproved years ago (*cf.* J., 1902, 587). Little mention is found of the important hexabromide test, whilst the obsolete Livache test, and other more or less unknown methods, occupy too much space. The description of turpentine and its substitutes, their preparation, composition and properties are adequately treated.

The cleansing, garbling, crushing and, later, the running of gums, both at the ordinary pressure and in the autoclave, are ably described, and the boiling of the oil to be subsequently added is given, together with numerous recipes for special varnishes. A discussion of the action of driers on oils follows the latest theories with regard to their action on raw oil, but one is surprised to find reference to zinc salts, as, if pure, they have no drying action. No mention is made of the work of Morrell (*cf.* J., 1915, 108) on the polymerisation of unsaturated oils under

the action of heat, or the bearing of this on the character of the film left on drying, nor is there any reference to the greater permanency of a polymerised ("polyolin") film compared with that of an oxidised ("linoxyn") one, and the relation of "super-oxidised" oil to this matter (*cf.* Ingle and Woodmansey, J., 1919, 101).

The volume is very comprehensive, but it leaves an impression that the author has omitted some useful work published in English journals of late years. Nevertheless, the book covers the subject more fully than any English or German work known to the writer, and the only adverse criticism to be made is that the arrangement of the subject matter causes the details to be diffused, instead of being confined under their particular subject titles.

HARRY INGLE.

AN INTRODUCTION TO THE CHEMISTRY OF PLANT PRODUCTS. VOL. I. ON THE NATURE AND SIGNIFICANCE OF THE COMMONER ORGANIC COMPOUNDS OF PLANTS. *By* PAUL HAAS *and* T. G. HILL. *Third edition. Pp.* xiii.+414. (*London and New York: Longmans, Green and Co.* 1921.) *Price* 16*s. net.*

In the preface to the first edition of this book the authors explained that it was designed to meet the needs of students of vegetable physiology, whose chemical knowledge is frequently "deficient in just those branches of chemistry which are of particular importance to the botanist, which is no doubt largely due to the fact that those compounds, which are of interest to the botanist, do not necessarily fit into the scheme of instruction of the chemist." Though nearly nine years have elapsed since then, this statement remains true, and the third edition of the book is on much the same lines as the first, with the exception that certain sections have been added to or rewritten, and that it is now issued in two volumes. Volume I is similar in scope to the full work in the two earlier editions; Volume II, which is to be published subsequently, will deal with physiological problems more fully than has been attempted hitherto.

The fact that the book is now in its third edition shows that it is meeting a real need on the part of students. The subject matter is arranged roughly into groups of products, *e.g.*, fats, carbohydrates, glucosides, tannins, pigments, nitrogen bases, etc. Hydrocarbons are omitted in spite of the fact that plant constituents include such an interesting and varied collection of substances of this class as paraffins, terpenes, rubber and gutta-percha. Similarly resins and essential oils are excluded.

The contents of the various sections seem quite adequate and up-to-date, so far as scientific information is concerned. It is doubtful whether it is worth while to include quite so much elementary chemistry as is given in the section on fats, oils and waxes. No one could read this book with profit without a considerable knowledge of chemistry, and for such readers it is surely unnecessary to explain what is meant by a paraffin and to set out in full the constitutional formulæ for ethane and propane (p. 9). Further, to rise from this to the complex Windaus formula for cholesterol (p. 17) in nine pages argues a greater absorptive capacity and more aptitude for the niceties of constitutional formulæ than the average beginner possesses. Much of the analytical detail concerning oils and fats could also be omitted as it is readily available elsewhere. In dealing with tannins no attempt is made to describe the estimation of tannin, and the section gains by the omission.

To readers of this journal there is no need to enlarge on the commercial and industrial importance of plant materials—the existence of such industries as those dependent on rubber, oilseeds, foodstuffs, fibres and cotton is an ever-present reminder of the great interests concerned in them. The authors exhibit a laudable desire to emphasise the economic side of the subject by frequent references to the industrial uses of the products they describe and to the processes employed in their preparation. Some of this information needs more thorough revision than it has received. For instance, though it is admittedly difficult to give a crisp, complete and accurate description of a varnish, one of the things it probably never is, is a "mixture of boiled oil with gum resins and oil of turpentine," if the term "gum resins" is used accurately.

The subsection on the "Industrial Uses of Vegetable Fats and Oils" omits all reference to palm-kernel oil except as a soap material, says nothing about the use of cottonseed oil for edible purposes, and states that palm oil has a faint odour resembling that of violets. In making the latter assertion the authors are in good company, but the statement is usually made with the qualification that the oil has this odour when fresh, and as few Europeans have the chance of smelling it in this condition the assertion in this form is more or less credible, but one would hardly associate violets with ordinary palm oil as it reaches this country.

Most of these remarks, it will be seen, refer to the chapter on oils and fats which, however, it is only fair to say, is the weakest portion of the volume. Taken as a whole the book fulfils the objects the authors had in view in writing it, and is in most respects a useful summary of well-selected information regarding those constituents of plants that are of primary importance to the physiologist and the biochemist.

MR. JOHN ALLAN IN THE CHAIR.

THE INORGANIC CONSTITUENTS OF COAL WITH SPECIAL REFERENCE TO LANCASHIRE SEAMS.

BY F. S. SINNATT, M.B.E., M.SC.(TECH.), F.I.C., M.I.MIN.E.; A. GROUNDS, B.SC.(TECH.), A.I.C.; AND F. BAYLEY, M.SC.(TECH.), A.I.C.

This paper describes a stage in the study of the inorganic constituents of certain typical seams in the Lancashire coalfield, and records a part of an investigation of the various coals from a number of viewpoints. The work has been carried out under the auspices of the Lancashire and Cheshire Coal Research Association.

It is well known that the coals in the Lancashire coalfield contain, as a rule, a low percentage of inherent ash. Of twenty distinct seams examined recently, none contained more than 6% of ash, whilst a great number contained less than 3%. Bickershaw Yard coal contained as little as 0·8%. The coals vary in properties from those which are practically non-caking to one (Mountain Mine) which possesses probably the highest caking power of any known coal, and yields a perfect metallurgical coke.

In distinguishing the coals the names in most common use have been adopted, but it must be recognised that other terms may be applied to the same seams in different localities.

For the purposes of this paper only the natural inorganic constituents of the seams have been considered. Every care was taken in obtaining the samples on which the work was carried out. A solid pillar was cut from the whole seam the cross-section of which was from 6 to 18 ins., according to the ease with which the coal could be handled. The piece of coal was packed in a box, and carried to the laboratory for examination.

The present investigation included the following objects:—

To determine if any relationship could be established between the composition of the white partings (ankerites) and the ash produced when the coal is incinerated.

To attempt to trace the source of the carbon dioxide evolved when coal is treated with mineral acids.

To investigate the form of combination in which iron exists in the coal substance.

The last subject is of interest in view of the fact that according to the work of Powell and Parr (Bulletin 111, University of Illinois) the greater proportion of the iron present in certain American coals occurs in the form of pyrites, and with this fact is associated the assumption that the iron does not enter into the preliminary stages of the oxidation of coal.

It would appear from the experiments described in the present paper that a proportion of the iron in Lancashire coals exists in the ferrous state, either in the white partings (or ankerites) or some other form of combination.

Most coal seams contain a proportion of white inorganic partings, of which no study has appeared in the literature. It will be seen later that the material may be considered either as substituted calcium carbonate, or as dolomitised siderite. The term ankerite, which is the one generally accepted in mineralogy for compounds having a similar constitution, has been adopted to distinguish the substance of the white partings.

The ankerites occur in the form of sheets varying in thickness from ⅛ in. to a mere film, at right angles to the bedding plane and on the face of the coal, but also frequently on the end of the coal. The layer of material may be so thin as to be transparent, and its presence can only be detected by the fact that after being allowed to stand in the air the coal becomes covered with an opalescent film, consisting of oxidised ankerite. When ankerite occurs adjacent to a band of vitrain it is frequently perfectly white in colour, whilst portions in contact with clarain or durain are comparatively dark, and impregnated with fine coal. It has been observed that a band of ankerite frequently terminates at a point where a layer of fusain occurs. The latter material is highly porous in nature, and it would appear that the ankerites have been deposited from a liquid medium which has travelled horizontally along the layer of fusain.

The ankerites form a distinct line of weakness in the coal, and if the latter is treated with dilute mineral acids, marked disintegration of the lumps is produced, owing to the decomposition of the compounds. The whole of the specimens examined contained varying percentages of iron practically entirely in the ferrous condition, and it will be seen from the analyses that certain examples contained a distinct percentage of manganese.

Average specimens of the ankerites from a number of seams have been analysed, and the results are given in the following table:—

TABLE I.

Percentage composition of the white partings (ankerites).

	Lower Mountain Mine.	Arley.	Ravine Mine.	Sapling Mine.	Hoo Cannel.	Rushy Park.	King Mine.
	%	%	%	%	%	%	%
Calcium oxide..	27·40	28·56	29·94	42·79	30·08	28·76	30·84
Magnesium oxide	13·33	11·51	16·15	0·41	11·18	8·74	5·76
Ferrous oxide..	14·56	9·81	4·80	13·07	14·16	16·23	18·42
Manganese oxide	—	0·82	1·11	—	—	0·59	0·31
Carbon dioxide	45·21	41·52	44·35	41·88	44·58	42·46	42·03
Silica	—	6·05	2·25	1·70	—	2·45	—
Ferric oxide ..	—	0·60	0·25	0·17	—	0·63	—
Pyrites ..	—	1·11	—	—	—	0·09	2·47
Equivalent to:							
Calcium carbonate	48·93	51·00	53·14	76·41	53·70	51·36	55·08
Magnesium carbonate ..	28·30	24·07	33·65	0·66	23·48	18·28	12·10
Ferrous carbonate	23·46	15·81	8·40	21·68	22·82	26·18	29·68
Manganese carbonate ..	—	1·33	1·80	—	—	0·96	0·50
Calcium sulphate	—	—	0·44	—	—	—	—
Silica	—	6·05	2·25	1·70	—	2·45	—
Ferric oxide ..	—	0·60	0·25	0·17	—	0·63	—
Pyrites ..	—	1·11	—	—	—	0·09	2·47

Specimens of ankerite obtained from the different layers in certain seams differ considerably in composition; the following analyses show the greatest variation yet encountered:—

TABLE II.

Ankerite from seam 8ft. thick.

	Top 15 in.	Bottom 7 in.
	%	%
Silica	0·91	2·25
Calcium carbonate	52·09	53·14
Magnesium carbonate ..	29·74	33·65
Ferrous carbonate	16·15	8·40
Manganese carbonate ..	1·41	1·80
Ferric oxide	0·33	0·25
Calcium sulphate	nil	0·44

The compounds undergo oxidation on exposure to air and become covered with reddish-coloured ferric compounds.

The following analyses show the change in composition which occurred when a specimen of ankerite was exposed to the air in contact with the coal. It should be pointed out that the two specimens of ankerite were of necessity obtained at a slight distance from one another and some small difference in chemical composition was detected:—

TABLE III.

	Sample freshly mined. Colour: white.	Sample after exposure to air for 12 weeks. Colour: red.
	%	%
Ferric iron	0·33	0·91
Silica	0·91	0·17
Ferrous oxide	9·29	10·58
Manganese oxide	0·87	1·08
Calcium oxide	29·17	29·31
Magnesium oxide	14·22	13·32
Carbon dioxide	44·67	44·74

The oxidation of the ankerites is influenced by the presence of carbon dioxide and water. As would be expected, the compounds are freely soluble in water in the presence of carbon dioxide, and the solution which results rapidly undergoes oxidation in the presence of air, with the precipitation of basic ferric compounds.

No accurate method of determining the percentage of ankerites in coal has been elaborated, but an approximate value was obtained for one sample of coal by crushing about 1000 g. until it would pass through a sieve of 4's mesh, and separating all the ankerite that was visible by picking it out with forceps. The coal contained 4·2% of total ash and 3·0% of ankerite. The equivalent weight of ignited ankerite was 1·7%, *i.e.*, 40·5% of the ash was derived from the ankerite present.

Samples of the coals from which the ankerites described above were obtained were incinerated at a temperature of 900° C., and the resulting ashes were analysed with the following results:—

TABLE IV.

Composition of coal ashes.

	Lower Mountain Mine.	Arley.	Ravine Mine.	Sapling Mine.	Hoo Cannel.	Rushy Park.	King Mine.
	%	%	%	%	%	%	%
Silica	40·20	43·21	35·00	38·92	32·98	25·49	29·45
Ferric oxide	25·66	12·38	9·99	48·40	23·34	38·80	26·32
Alumina	25·41	28·47	31·58	3·68	26·86	20·61	29·53
Calcium oxide	3·52	7·12	11·63	5·04	6·88	7·08	5·96
Magnesium oxide	1·98	2·36	2·45	0·50	3·10	3·22	0·11
Sulphur trioxide	2·02	4·30	7·68	0·16	3·04	1·25	1·98
Alkalis and loss	1·21	2·16	1·67	3·30	3·80	3·55	6·65
Percentage of ash in the coal	3·00	3·20	5·20	4·00	24·4	12·4	4·6

A comparison of the above results shows that the proportion of the various constituents occurring in the ash is not by any means parallel with that found in the ankerites.

The percentage of carbon dioxide evolved when the coals were treated with mineral acids was determined by a method described in Bulletin No. 7 of the Lancashire and Cheshire Coal Research Association, from which the following results are extracted:—Mountain Mine, 0·57% CO_2; Arley, 0·18%; Ravine, 0·32%; abnormal sample I., 6·85%; Pemberton 2 ft., 0·72%; Garswood 9 ft., 0·44%; Hoo cannel, 1·84%; Rushy Park, 0·76%; Lower King, 0·77%; Bickershaw Yard, 0·40%.

It was thought that it might be possible to calculate approximately the proportion of the ankerite in a particular seam by the above determination, but it was found that the percentage of carbon dioxide evolved was in excess of that required to combine with the whole of the bases occurring in the coal as ankerites.

The following example shows the result obtained if the carbon dioxide evolved is assumed to be derived solely from ankerites:—

TABLE V.

1. Lower Mountain Mine.

Ash = 3·03%. Carbon dioxide = 0·57%.

Constituents.	Coal ash original analysis (100 g.).	Gross constituents of coal ash in 100 g. of coal.	Ankerite analysis.	Ignited ankerite equivalent to CO_2 in 100 g. of coal. g.
Silica	40·20	1·218	—	—
Ferrous oxide	nil	—	14·56	—
Ferric oxide	25·66	0·779	—	0·314
Alumina	25·41	0·770	—	—
Manganese oxide (MnO)	—	—	—	—
Calcium oxide	3·52	0·106	27·40	0·533
Magnesium oxide	1·98	0·059	13·33	0·263
Carbon dioxide	—	—	45·2	—
Sulphur trioxide	2·02	0·061	—	—
Pyrites	—	—	—	—
Alkalis and loss	1·21	0·036	—	—

From the above consideration it will be clear that the amount of carbon dioxide evolved when coal is treated with mineral acids is more than sufficient to combine with the bases found in the inorganic constituents of the coal, and must be derived from other sources than ankerites.

The source of the carbon dioxide has not been traced accurately, but it will be shown later that a portion of the iron in coal probably occurs as ferrous carbonate, as distinct from that occurring in the ankerites. The percentage of carbon dioxide is, however, of some interest from an analytical point of view. Unless the amount of carbon occurring as carbon dioxide is deducted from that found by combustion of the coal the percentage of organic carbon will be too high. The percentage of carbon dioxide should be deducted from the percentage of volatile organic matter, as presumably the whole of the carbon dioxide is evolved at a temperature of about 900° C. In the case of the abnormal sample, the volatile organic matter determined was too high by 6·8%.

Mr. N. Simpkin, in collaboration with one of us, is continuing certain phases of the work, and has treated the coals with dilute hydrochloric acid, and determined the amount of iron which passes into solution; the total amount of iron present was also found.

It appeared desirable to ascertain what proportion of this iron occurred in the ferrous state, and specimens of the fresh coal were treated with hydrochloric acid (10%) in an atmosphere of carbon dioxide. The excess of coal was removed by filtration in an atmosphere of carbon dioxide, and the amount of iron in the filtrate determined. It was found that the liquid contained a negligible quantity of iron in the ferric condition. The iron in the ferrous condition was determined by oxidation and subsequent titration with a standardised solution of titanous chloride. As this examination had to be performed on fresh samples of coal the results are not exactly parallel with those previously quoted. The preliminary results are, however, strictly comparative, and are given in the following table:—

TABLE VI.

	Total iron. %	Iron (ferrous) extracted with hydrochloric acid. %	Iron (ferrous) extracted with hydrochloric acid. Percentage of total iron.
Rushy Park	0·494	0·176	35·6
Lower Mountain Mine ..	1·779	0·535	29·7
Arley	0·612	0·047	7·7
Ravine	1·379	0·205	14·9

The results quoted in this paper are of interest as indicating that a distinct percentage of the iron in coal, which differs widely in different seams, is present in the ferrous condition in the ankerites, and in some other form of combination; it does not necessarily follow that the iron extracted by means of hydrochloric acid is present in the coal in the ferrous condition, since it may have been produced by the action of coal upon ferric compounds. In certain cases distinct oxidation of the ankerites can be detected within a month of the seam being obtained from the mine.

From a chemical standpoint it will be of interest to obtain information as to the relative rates of oxidation of ankerites of different compositions, and the effect of this oxidation upon the oxidation of the coal substance and of pyrites. It is not obvious which type will most readily oxidise, but upon the behaviour of these compounds will depend the degree to which coals will weather, and as a corollary their properties during storage.

Oxidation obviously produces a change in volume or thickness of the sheets of ankerite, and consequently is a factor contributing towards the disintegration of masses of coal. When coal has been allowed to stand for extended periods, oxidation of sheets of ankerites has been observed at a considerable depth into the coal. Up to the present no direct evidence has been obtained as to whether the primary heating of coal can be connected with the presence of ankerites, and the effect of manganese etc. upon the general action of the ankerites. At the same time, in view of the clearly recognised action of ferrous and manganese carbonates as catalysts it appears of considerable interest to examine the subject in the light of the information described in this paper It would also appear that carbon dioxide may be an active agent in the oxidation of the compounds; we have found that ankerites are freely soluble in water containing carbon dioxide, and that the resulting solution rapidly undergoes oxidation with precipitation of the iron in the form of ferric compounds. In a mass of coal evolution of carbon dioxide is known to take place, and in the presence of any excess of moisture the conditions are such as to bring about the oxidation of the compounds, with carbon dioxide and water taking part in the reaction.

When coal containing ankerites is burned, bands of residue from the ankerite will remain separate from the inherent ash of the coal unless the temperature is sufficiently high to fuse the whole mass. The residual material from the ankerite will consist of highly infusible oxides. It would follow that coal which has been broken to a small size will contain the ankerite and silicious coal ash in more intimate contact than when larger sizes are used.

Analysts make a practice of quoting the colour of coal ashes, and it is well known that such ashes consist of a mixture of particles widely different in colour. We therefore made it a rule to pulverise coal ashes to a fine powder (1/200 mesh) in order to obtain an impression of the colour as a whole.

DISCUSSION.

The CHAIRMAN suggested that the authors might determine how it was that the ankerites themselves were provocative of the oxidation of the coal material. If a portion of the coal were mixed with definite quantities of the ankerites it might be possible to determine how far the ankerites themselves were excitants of the coal oxidation. It might also be interesting to determine whether any of the particular seams of coal mentioned as containing manganese exhibited any greater tendency towards heating in the mass than those which were free from it, in view of the well-known catalytic effect which manganese possessed as an oxidation exciter.

Mr. H. L. TERRY said that as many of the analyses showed such low amounts of iron and manganese carbonates the term "ankerite" did not seem particularly appropriate. Certainly such terms as "dolomitic siderite" or "sideritic dolomite" were cumbrous and not to be recommended. He had often found coal partings to be of a dolomitic nature, but one sample he had had from the Lower Mountain Mine coal at Rishton, near Accrington, was pure calcite. Was this consistent with the authors' investigations? He noticed a great variation in the amounts of iron carbonate in the analyses quoted, and in many cases the manganese did not rise above what was ordinarily found in some limestones. Ankerites were not uncommon in the dolomitic beds of the lower carboniferous limestone in Derbyshire, and they were probably more widely distributed than was generally supposed. A peculiar manganese ore known as wad used to be obtained to a considerable extent at one time from pockets in the limestone adjacent to some of the mineral veins in Derbyshire. He had found that the oxides of manganese and iron were always mixed with magnesia, and he thought that the obscure origin of these deposits could be attributed to the action of carbonic acid on ankerite deposits. This was a matter he intended to probe further. At the Killeen copper mine, Co. Tipperary, the ore was associated with well crystallised ankerite showing about 30% each of the carbonates of calcium, magnesium, and iron, with 6—7% of manganese carbonate.

Mr. WILLIAM THOMSON enquired what was meant by the "face" and the "end" of the coal, and also what process was adopted for estimating the carbon dioxide when the coal was treated with hydrochloric acid. Was it possible that some of the sulphides of iron in the coal would give off hydrogen sulphide which might be estimated as carbon dioxide? The authors had suggested various explanations as to why coal might become heated or take fire, but the usual explanation was that the oxidation of the pyrites produced the heat and fire.

Mr. STEVENSON asked whether the experiment had been made of grinding coal in a fairly high vacuum. Coal contained large quantities of occluded gaseous matter. Was there any possibility of carbon dioxide being occluded in the coal and set free on treatment with acid? If a sample of coal from one of the seams were treated with a ferric salt, say ferric chloride, and hydrochloric acid, a portion of the ferric chloride might possibly be reduced to the ferrous state. If so, that would lead somewhat to a modification of the view that the ferrous condition was the only one found.

Mr. MCCULLOCH said that he had been unable to find any calcium or magnesium in the clays associated with some of the Lancashire coal seams. Could any theory be put forward as to how the ankerite came to be in the coal? If the ankerite was carried by a hard water, then it would appear that the surfaces of the under and over clays should

contain considerable quantities of calcium and magnesium.

Mr. Booth suggested that the ankerites were due to water infiltration from the limestone; the presence of comparatively high percentages of magnesium and manganese suggested this. The ferrous iron was no doubt derived from the chlorophyll present in the green parts of the coal measure flora. One would, of course, expect to find quite high percentages of ferrous carbonate. Coals which were liable to spontaneous ignition usually contained microscopically small yellow grains, as pointed out by Lomax. The possibility of these being chlorophyll grains should not be overlooked. The variation in the percentage of iron in the ankerities might be accounted for by the varying iron content of this coal seam, due to difference in constitution.

Mr. Grounds said that although Capt. Sinnatt has advanced no definite theory as to the connexion between ferrous carbonate, manganese carbonate, and spontaneous ignition, he had nevertheless hinted that there might be a connexion between these three factors. The South Wales bituminous coals contained 19—30% of volatile organic matter, as compared with 23—40% in the Lancashire coals. He thought it was generally agreed that spontaneous combustion was more liable to take place in coals containing a high percentage of volatile organic matter than in those containing a low percentage. Spontaneous ignition very rarely occurred with anthracites or steam coals. Ankerites were not present in the South Wales bituminous coals to anything like the same extent that they occurred in the Lancashire coals, and travelling westward from the Cardiff valleys towards the Swansea area, *i.e.*, the anthracitic centre, there was a gradual transition in the same seam from a bituminous coal which contained 23% of volatile organic matter to an anthracite containing only 9%. At the same time there was another transition in the Eastern coals containing, say, 23% of volatile organic matter. There were quantities of ankerite visible, yet not so visible as in the Lancashire coals, while among the anthracites there were scarcely any ankerites at all. It seemed rather peculiar that the coals which possessed the highest volatile organic matter should have also the highest quantity of ankerites and also were the most liable to spontaneous ignition.

Mr. Bloch asked whether Capt. Sinnatt had adopted any process to separate the alkali from the coal.

Mr. Varley referred to the figures in table III. showing that the result of exposing ankerites to air was to increase the ferric iron from 0·33% to 0·91%, whilst there was an increase in the amount of ferrous oxide from 9·29% to 10·58%; another remarkable point was the diminution of the silica from 0·91% to 0·17% after 12 weeks' exposure. Did the analyses shown give the composition of the same uniform sample before and after exposure to air, and if not could such results be relied upon for purposes of comparison?

Mr. Taylor mentioned that a piece of Mountain Mine coal weighing about 4 lb. was exposed to the air for about 13 months, at the end of which time the surface of the coal was covered with a white powder. When the coal was digested in water and the solution examined, the iron constituent was found to be in a ferrous condition. The solution also contained ammonium and sulphate in the proportions of one of ammonium to 40 of iron and 40 of sulphate. The oxidation or sulphating of coal might not be attributable to the iron in the coal.

Dr. A. C. Dunningham said that the authors' investigation into the nature of coal ash might be of great service owing to the well-recognised fact that the practical value of coal depended not only on its theoretical heating value, but on the nature of its ash. It might also be of value in yielding information which would lead to a method of purifying coke. This was probably even now the cheapest form of carbon, which for some purposes was required in a very pure form.

Captain Sinnatt, in reply to Mr. Varley, said that it was necessary to leave half of a piece of ankerite on the coal to stand for 12 weeks, whilst the other half was analysed. The same sheet of ankerite was used, but, as had been indicated in the paper, this material was not by any means constant in composition, and consequently the analytical figures for material one inch or so apart might be different. The silica in different samples might vary widely, as it was found deposited on the face of the material in local aggregations. It would be necessary, therefore, to accept these results until some better way of comparing the analyses could be adopted. The analyses only emphasised the point that considerable variations in the composition of the ankerites must be expected in a very short distance. The suggestion made by Mr. Allan was valuable, and if a method could be elaborated experiments would be carried out to test the influence of different percentages of manganese upon the oxidation of coal. In one part of the Ravine Mine the ankerite contained 4% of manganese, and although this observation was an isolated one, it was well known that the Ravine was the most liable to fire of any of the coals in the Lancashire coalfield. The remarks of Mr. Terry were of considerable interest, and it was most important that some name should be generally adopted for these white partings. The Lower Mountain Mine was, in certain parts, characterised by having a roof largely composed of marine fossils. It was quite possible, therefore, that intrusions of pure calcite would be found in it. The observations on the dolomites were especially pertinent. The terms "face" and "end" were used as applied in the coal industry, the face being the portion of the seam at which the collier worked, as the coal tended to fall in sheets towards him, owing to the line of weakness formed by the ankerites, etc. The end was at right angles to the face, and contained less of the partings. The method used for the determination of carbon dioxide was one elaborated by one of the authors (Sinnatt, Analyst, April, 1913); the contamination of the gas by hydrogen sulphide was not possible. The question of the influence of the pyrites upon the oxidation of coal was a debatable one, and had not been introduced into the paper, as Mr. Lomax of Bolton was at present engaged upon a systematic examination of the subject. Every endeavour had been made to eliminate occluded carbon dioxide. Each sample of coal was boiled with water for 20 minutes, in order to eliminate the occluded gases. The suggestion that the action of ferric chloride on coal should be examined was a valuable one; it was well known that iron pyrites had a reducing action on ferric chloride, but the exact action of the coal substance upon ferric chloride had received little attention. The authors agreed that the ankerites were distributed throughout the coal substance, and their thoughts tended to an opinion that some of the iron might be present in the coal in the form of an organic compound. The suggestion made by Mr. Booth that the iron was derived from the chlorophyll in the vegetation from which the coal was formed would account for practically all the iron found in coal seams. It was proposed, at a future date, to attempt to separate the ankerites by the froth flotation process. With reference to the remarks of Mr. Taylor, it would appear that he had been dealing with a deposit formed on the surface of the coal.

NEW PROCESS FOR THE VULCANISATION OF RUBBER.

BY S. J. PEACHEY AND A. SKIPSEY.

The importance of the vulcanising process as one of the essential operations in the manufacture of all rubber goods is perhaps not fully appreciated, except by those who are directly connected with the industry; yet it may be said without exaggeration that but for the timely discovery of the process by Goodyear in 1839 the then newly-founded industry would not only have failed to attain its present position and magnitude, but would almost certainly have retrogressed.

Although it yields a vulcanised rubber of excellent quality, the Goodyear process itself possesses certain disadvantages, the chief of which are as follows:—(1) It necessitates the continuous use of steam both as a heating agent and as a medium for exerting pressure on the goods under treatment (and thus avoiding the development of porosity). (2) It is a comparatively slow process. (3) It restricts the manufacturer in his choice of filling and colouring agents. Organic filling agents, with very few exceptions, are destroyed or seriously deteriorated by the combined action of heat and sulphur, and in many cases by heat alone. Thus cheap and useful filling materials such as wood meal, leather, cotton, and wool wastes cannot be successfully employed in the manufacture of rubber goods. The manufacturer has to fall back on inorganic compounding materials such as barytes, chalk, china clay, kieselguhr and the like. Further, the majority of coal tar dyestuffs are destroyed or modified by the action of sulphur at a temperature of 140° C., so that the manufacturer has to confine himself to the use of mineral pigments such as zinc oxide, antimony sulphide, chrome green, and so on, a fact which explains the rather drab colours common to most rubber goods. Delicate tints are practically unobtainable.

The new process which forms the subject of this paper removes these restrictions and renders possible the production in the rubber trade of wholly new technical and artistic effects. The discovery of the process resulted from an investigation on the behaviour of rubber towards different forms of sulphur. Sulphur is remarkable for the number of allotropic forms which it is capable of assuming. In all three states of aggregation—solid, liquid, and gaseous—sulphur appears to be capable of varying its molecular complexity. An attempt was made to compare the action of these different forms of sulphur on rubber, and this attempt was interrupted by the discovery that the interaction of sulphur dioxide and hydrogen sulphide produces momentarily a form of sulphur which rapidly combines with rubber at the ordinary temperature, yielding an effective vulcanisation. The reaction between the two gases must take place in contact with the rubber or no vulcanisation results. In other words, the liberated sulphur is active only at the moment of its liberation, and it is fair to assume, therefore, that the effect is produced by atomic sulphur.

In applying the new process the rubber is exposed alternately to the action of sulphur dioxide and hydrogen sulphide. The gases readily diffuse into (probably dissolve in) the rubber, and there interacting produce active sulphur, which immediately combines with the rubber at the ordinary temperature, yielding a product wholly comparable with that obtained by the Goodyear hot process. Evidence is accumulating to show that the product is actually superior in strength; this may be explained by the fact that the depolymerisation of rubber produced by heat is avoided in the new process.

The process appears to be of fundamental importance for the following reasons:—

(1) It is a true sulphur vulcanisation—as distinct from the sulphur chloride vulcanisation produced by Parkes' "cold cure."

(2) It eliminates the use of heat and to a great extent the use of mechanical pressure.

(3) It employs two gases, both of which can be produced on a large scale at a very cheap rate.

(4) It is rapid in action.

(5) It enables the manufacturer to employ organic filling agents which cannot be used in conjunction with the hot process or with the Parkes process (most organic materials are attacked and destroyed by contact with sulphur chloride).

A number of cheap and highly durable materials may be fabricated from various wastes in this manner and employed as floor and wall coverings, for boot and shoe manufacture, and for fancy leather goods and upholstery work. Further, in numerous manufacturing processes unconnected with the rubber industry the process renders possible the use of rubber as a binding agent for fibrous and granular materials as an alternative to the resins, bitumens, gums, and like substances which have hitherto been employed, with the result that the toughness and flexibility of the products are considerably increased.

(6) Coal-tar dyestuffs and even natural dyes like chlorophyll, which, with a few exceptions, are destroyed by the hot cure and also by the sulphur chloride cure, can be introduced into rubber mixings to be cured by the new process with the production of delicately-tinted materials hitherto quite unobtainable.

The process possesses the advantage of extreme simplicity, and its translation from the laboratory to the works should prove a simple matter.

The process can be extended to the vulcanisation of rubber in solution. If a solution of rubber in benzol or naphtha be saturated or partly saturated with hydrogen sulphide and mixed with a solution of sulphur dioxide in the same solvent, the liquid sets in a few moments to a stiff jelly, and on eliminating the solvent by evaporation a fully vulcanised rubber is obtained. The use of the mixed solutions for producing perfectly vulcanised seams and joints has proved highly successful, and inner tubes repaired by the new process have an excellent life.

Further, by the use of the solution process, re-formed leather soles and heels may be attached to boots without the aid of stitching or nailing, and, indeed, a whole boot may be produced from the re-formed leather without a single stitch being necessary.

During the past month or so certain modifications of the process have been devised, but these must form the subject of a later paper.

Discussion.

Mr. Bailey asked whether the presence of the sulphur dioxide or the hydrogen sulphide in the rubber was likely to result in deterioration of the rubber in use. Also whether the removal of the gas was complete.

Mr. Tomkinson asked if the water produced caused any porosity in the finished goods.

Mr. Marcroft pointed out that one of the best red pigments was antimony sulphide, and that it usually contained a fair percentage of free sulphur. The same remark applied to ultramarine. Was that free sulphur affected during vulcanisation, or would it "sulphur up" afterwards?

Mr. LEON said that he had made experiments with the process described and had found that quite a lot of sulphuric acid was formed. How was this got rid of? He assumed that there was a certain amount of free sulphur in excess at the end of the process; did that "bloom" up and, if so, what method could be adopted for its prevention?

Dr. BLOCH asked how the new rubber compared with leather or with rubber vulcanised by the hot process in the wear of boots and shoes.

Mr. TERRY said that he had examined a sample of the rubber treated according to the authors' process, and after a lapse of six months in his possession he had found it to be perfectly sound. The problem in the rubber world was to find a really satisfactory "ageing" test. In order to obtain proof that rubber was properly vulcanised and not surface-cured the de-vulcanising processes could generally be employed. Rubber "cold-cured" by the Parkes process could always be de-vulcanised quite easily, especially in hot alkali, which removed the chlorine; but if the rubber cured by the "Peachey" process was treated by a hot alkaline solution there was practically no effect; the strongly vulcanised rubber remained intact. That was evidence of complete vulcanisation and not merely "surface curing," as in the Parkes process.

Prof. GREEN asked whether the process could be applied to the treatment of outer covers for tyres. It would appear that if it was possible to combine the strength of a fibrous material with the resiliency of rubber a great advance might be made in the wear of outer covers.

Mr. G. H. GRAY asked how it was proposed to manufacture a solid rubber tyre such as was used on a commercial vehicle.

Mr. PEACHEY, in reply, said that the two gases were introduced separately, both being comparatively easily soluble in the solid rubber, especially the sulphur dioxide. The amount of sulphur dioxide absorbed by rubber was surprising. Hydrogen sulphide was more than sufficiently soluble to yield a coefficient of vulcanisation up to, say, 5, which was higher than was required in practice. Adsorption was not relied upon at all, but absorption of the gas followed probably by solution. Generally speaking, excess gases, as far as could be judged by smell, were driven out of the rubber after about one hour's exposure. The practice had been followed throughout of giving the shorter sulphur dioxide treatment first and finishing up with the H_2S in excess, so that there was very little possibility of free SO_2 remaining and practically no danger of free acid forming. To get a fully vulcanised rubber it was only necessary to introduce some 2½% of sulphur; therefore the amounts of the two gases required to vulcanise a mixture containing, say, 50% of rubber were surprisingly small, and there was only a negligible amount of water produced. The water diffused out of the rubber quite rapidly; it never existed in the liquid form in the finished product, and the vulcanisation need not be followed by any drying operation; mere exposure to the air for a few hours, at any rate, caused all necessary elimination of water. As regards the free sulphur present in antimony sulphide and ultramarine, it was disadvantageous to have free sulphur present in a mixing which had to be vulcanised by the new process. He supposed it tended in some way sympathetically to convert the atomic sulphur into molecular sulphur. In all mixings which were made for the new process ordinary sulphur would not be present, and the use of antimony sulphide would be especially avoided, as that substance could be replaced by much better and brighter colours. In the "dry" treatment the rubber or rubber mixing to be vulcanised was exposed to sulphur dioxide for 10 minutes, after which a very short exposure to the air was given to remove the adsorbed gas from the surface. The material was then introduced into another chamber where it was exposed to the hydrogen sulphide for 20 to 30 mins. In the case of "solution vulcanisation," it was very easy to prepare standard solutions, and in practice a standard solution of sulphur dioxide was prepared by weight. It was convenient to use a solution containing 0·8% of this gas in benzene, and to saturate a 10% rubber solution with hydrogen sulphide, and mix four volumes of the hydrogen sulphide solution containing the rubber with one volume of the benzene solution. The actual proportion of the two gases interacting was theoretical. Small amounts of free sulphur were invariably formed in the rubber. The combination was not quite complete, as apparently a small amount of the atomic sulphur was changed into molecular sulphur, but the amount was small compared with the amount that was left in the rubber by the "hot" process. It was a matter of surprise to learn that Mr. Leon had found acid in his samples; possibly he had used the sulphur dioxide in excess, or at any rate not in sufficient deficiency. In his own experiments the hydrogen sulphide had been invariably kept in excess, and by treating the rubber first with sulphur dioxide and then with hydrogen sulphide the formation of any trace of free acid could be avoided. If, however, faulty working led to the formation of a trace of free acid the material could be treated with ammonia, just as in the sulphur chloride process. The question of the treatment of rubber of one inch thickness was rather beyond the present limits of the process. The porosity of a mixing was actually greater when it was fairly heavily loaded, and it was surprising what penetration was obtained. Although exact diffusion figures were not available, it might be assumed that both sulphur dioxide and hydrogen sulphide diffused into rubber at least as rapidly as carbon dioxide, and in the case of sulphur dioxide more rapidly. They would not attempt by the new process to deal with material one inch thick, but would avail themselves of the new method of building up which had become possible as the result of the new solution process. It was possible now to build up material of any thickness after it had been vulcanised in sheets and to get a solid mass in which the joints were of a strength equal to that of the material itself. The treatment of thick articles would, therefore, involve new methods of building up, but it was quite desirable that such new methods should be introduced. The leather compounds prepared by this process were 2½ times as durable as new leather.

Liverpool Section.

THE CORROSION OF COKE OVEN WALLS.

BY A. E. FINDLEY.

The work described in this paper was undertaken with the idea of throwing some light on the effect of certain ingredients in the coking slack on the corrosion of the oven walls. The ingredients which were suspected of producing the most harmful effect were salt, iron, and moisture.

For the purposes of this work the total amount of salt present in the coals examined was not determined, but only that amount which could be removed by washing 200 grams of each coal by percolation with cold water under exactly similar conditions. The main object of this washing was to test the retentive capacity for water of different coals (as sent to the ovens), and also to show to what extent this retentive capacity depended on the fineness of the coals after crushing. Subsequently each coal was washed until 100 c.c. of the wash water required 2 c.c. or less of $N/50$ silver nitrate solution. In each case the same amount of wash water was used on a definite weight of coal. The quantity of salt extracted was proportional to the quantity actually present in the coal within certain limits.

the finest crushed slack was used, the coal in the hoppers is not saturated with water. The subjoined table indicates the first stages of the work for four different Yorkshire coking slacks.

The relative retentive capacities for water in the table are purely empirical and are based on the rate of draining under similar conditions.

The following conclusions may be drawn from the table:—

(1) As the amount of salt increases the durability of the oven walls decreases.

(2) If the amounts of both salt and iron present are high, as at Waleswood, durability seems to be still further diminished.

(3) Iron and moisture may be present in relatively large amounts, but this does not appreciably affect the durability of the oven walls if the amount of salt is very low, as at Hoyland Silkstone.

(4) The higher temperature in vertical flues of a regenerative oven system tends to shorten the life of the oven walls.

W. J. Rees has shown (*Cf.* Ceram. Soc., Spring, 1920) that iron may be carried right through and out of a fireclay brick by means of salt at 950° C. Working side by side with Rees I have endeavoured to throw some light on the mode of transference of iron from coal into the fireclay of the oven walls, because Rees has shown (Trans. Ceram. Soc., 1918) that spalling mainly takes place at a layer of hæmatite formed some distance inside the bricks; he explains the presence of hæmatite by assuming that the iron is carried into the bricks as chloride until it meets with oxidising conditions.

Tests on four coals in South Yorkshire.

Colliery.	Type of ovens.	Salt. %	Fe_2O_3. %	Water. %	Ash. %	Relative retentive capacity for water.	Relative fineness.	Life of ovens.
Waleswood ..	Simon-Carves. (*a*) regenerative (*b*) waste heat.	0·142	1·45	15·5	8·75	8	4·1% above ¼" 20·5% above ⅛" less than ¼" 21·1% above 1/16" less than ⅛" 54·3% less than 1/16"	(*a*) 18 months (*b*) 2¼ years roughly
Monckton Main..	Simon-Carves, waste heat.	0·086	0·82	11·5	9·0	3·4	16·25% above ¼" 41·5% above ⅛" less than ¼" 16·75% above 1/16" less than ⅛" 25·5% less than 1/16"	Roughly 3 years.
Wharncliffe Woodmoor	Simon-Carves, regenerative.	0·038	0·71	8·4	4·9	1	28·8% above ¼" 29·6% above ⅛" less than ¼" 14·3% above 1/16" less than ⅛" 27·3% less than 1/16"	Roughly 4 years.
Hoyland Silkstone	Semet-Solvay, waste heat.	0·028	1·09	12·4	8·05	29	1·43% above ¼" 9·34% above ⅛" less than ¼" 12·05% above 1/16" less than ⅛" 65·98% less than 1/16"	No repairs since 1917 when ovens were built.

J. W. Cobb has shown that, however finely a coal be crushed, washing with cold or boiling water does not remove all the salt, and that further prolonged boiling with water and with dilute nitric acid will yield further quantities of salt; consequently, the figures given for salt in this work are better for the purposes in view than figures taken from the average results over one year's working at the coke ovens using the coals examined, because they have been obtained under almost exactly similar conditions, whilst the conditions for the determination of salt at different coke ovens are very variable.

The amount of water in the coal going to the hoppers will be dependent initially on the size of the unwashed coking slack; the amount of water retained in the coal after crushing (*i.e.*, the amount of water which does not drain out, however long the coal remains in the hoppers) will depend entirely on the fineness of the crushing. The results obtained have proved this conclusively, and also that at the Hoyland Silkstone Colliery, where

The following experiments were carried out by heating 5 g. of thoroughly mixed coal (ground to pass a 30-mesh sieve) in silica tubes to 900° C.—950° C. under the conditions stated:—

Substance heated.	Period in hours.	Atmosphere.	Fe_2O_3 found in ash, calc. on. original coal %
Coal A	4½	Air	1·56
	4½	Steam and air	(a) 1·46 (b) 1·42
Coal + $CaCl_2$	4½	Air	1·42
"	4½	Steam & air	1·43
Coal	4½	Steam & air & HCl	1·28
*Coke	4½	Coal gas	1·53
Coal B	4½	Air	1·44
Coal, $MgCl_2$, & NaCl	4½	Air	1·32
*Coke, $CaCl_2$, & NaCl	4½	Coal gas.	1·32
Coal, $CaCl_2$, & NaCl	4½	Air & steam	1·42
*Coke	45	Coal gas	1·44

* Where coke is quoted it is the coke from 5 grams of coal.

It will be seen that the maximum loss of iron is obtained by burning the coal in an atmosphere of hydrochloric acid vapour and air. Chlorides appear to be capable of removing iron in the presence of air and steam or of coal gas, but coal gas alone is not effective in removing iron from coal or coke. Of the above results those with chlorides cannot be regarded as absolutely conclusive, as I have found that the majority, although all pointing to the fact that iron is removed, are not outside the limits of experimental error; for definite proof of the removal of iron it is necessary to depend on the result obtained with hydrochloric acid which, in my opinion, is quite beyond the limits of probable error of experiment. There is no doubt that chlorides have the same effect in the presence of gas and steam at the temperature of the ovens, as most chlorides likely to be present in coal will yield hydrochloric acid under the conditions existing in coke ovens.

A NEW METHOD FOR THE PRODUCTION OF CELLULOSE ACETATE.

BY W. LEIGH BARNETT, B.SC., A.I.C.

A variety of substances have been employed as catalysts of the acetylation of cellulose, the chief of which are strong dehydrating agents, such as sulphuric acid, phosphoric acid, zinc chloride, chlorides and oxy-chlorides of sulphur and phosphorus, dimethyl sulphate, chloroacetic acids, etc. Chlorine does not act readily unless under special conditions, and then only very slowly. Combined in the form of chloroacetic acids, large quantities are required compared with the weight of cellulose employed. Many of these catalysts possess the disadvantage that they give coloured or cloudy solutions owing to decomposition and degradation of the cellulose ester. Sulphuric acid, which is largely employed, tends to give dark-coloured solutions and also to hydrolyse the product, in addition to which the properties of the resulting esters vary considerably. Further, the films are generally brittle owing to the fact that all the sulphuric acid cannot be removed successfully. It is claimed that addition of substances which neutralise the effect of the acid, or other condensing agent, keep the syrupy solutions of cellulose acetate in good condition and prevent them from giving brittle products. A distinct improvement in the acetylation of cellulose results from the use of sulphuryl chloride as catalyst (Chem. Fabrik von Heyden, E.P. 24,382 of 1910), whereby superior cellulose acetate solutions result, and these solutions are not decomposed by the sulphuryl chloride.

For an investigation into the esters of cellulose it was necessary to make use of cellulose acetates which had been prepared in such a way as to ensure the minimum amount of change in the parent complex. All of the ordinary methods for acetylating cellulose were rejected on the grounds that either the ester solutions were coloured after acetylation had occurred, or that the solutions were not brilliantly clear, and for these reasons there was no guarantee that the esters when isolated would not contain products of degradation. By using a mixed catalyst of chlorine and sulphur dioxide I have found that satisfactory results are obtained with the minimum amount of change in the parent complex. If cellulose be treated with a suitable mixture of glacial acetic acid, acetic anhydride, and a trace of chlorine, practically no acetylation results unless the mixture be heated for some time. Similarly, if sulphur dioxide be substituted for the chlorine, no acetylation occurs, and if the mixture is heated it takes place to a smaller extent than in the case of chlorine. If, however, traces of both chlorine and sulphur dioxide be introduced, either separately or together, into the mixture, acetylation proceeds to a remarkable extent, and a perfectly clear, colourless solution, or even jelly results. By suitably choosing the conditions for the reaction it is possible to obtain a great variety of pure esters, possessing valuable properties of strength, film flexibility, transparency, and solubility. Acetylation proceeds at any temperature, and as no signs of discoloration occur, owing to the great ease of control of the reaction, no special precautions are necessary. The combined use of chlorine and sulphur dioxide is equally efficient in producing other esters, such as the butyrate, benzoate (using benzoyl chloride in acetic acid), etc.

The great reactivity of this mixed catalyst is probably due to the fact that first the cellulose itself acts as a condensing agent for the chlorine and sulphur dioxide, which produce small amounts of sulphuryl chloride in intimate contact with the cellulose, and these traces of sulphuryl chloride, being produced in *statu nascendi* under such conditions, are much more effective in promoting the subsequent acetylation.

A large number of experiments were carried out in order to ascertain the best conditions for the acetylation of various kinds of cellulose. Swedish filter paper, bleached and grey American cotton yarn, and cotton wool were employed, whilst variations in the method of adding the catalysts together with alterations in relative quantities and conditions of temperature were introduced. The best method for isolating the cellulose ester from the acetic acid solutions was found to consist in the addition of chloroform or acetone to the reaction solution, followed by mixing with an excess of water. When the volatile solvent is distilled out the cellulose acetate is gradually precipitated, due to the rising of globules of the chloroform solution through the water. The globules become covered with a fine film of precipitated cellulose acetate, and on stirring these are disintegrated. By this means the ester is obtained in the form of a fine white powder, and can easily be washed free from acid. The products can be dried at 100° C. for several days, and do not show any signs of decomposition or darkening in colour. The properties of film strength etc. are not impaired by continued heating.

The product depends on the conditions of acetylation. If the temperature be kept below 65° C., and only a trace of sulphur dioxide be employed, the product is chiefly a cellulose diacetate. If the ratio of chlorine to sulphur dioxide be nearer to unity then the product is mainly cellulose triacetate, particularly if the temperature be allowed to rise above 65° C.

The following table shows the nature of the products obtained after varying intervals:—

Time. Hrs.	Yield. %	Acetic acid. %	Cellulose. %
1	178	63·9	58·9
2	173	63·7	53·1
24	174	—	—
48	173	63·3	51·5
72	173	62·0	46·9
72	176*	61·9	48·8

* In this case there was formed in addition a small quantity (1·2%) of an acetate insoluble in acetic acid. Theoretical yield for cellulose triacetate, 178%; C 49·9%, H 5·6%. The product contained C 49·2%, H 5·3%.

In one experiment 200 g. of acetic acid, containing only sufficient chlorine to colour it, was poured on to 50 g. of filter paper, and after standing for some time 250 g. of acetic anhydride was added, followed by the passage of a few bubbles of sulphur di-

oxide. The temperature rose spontaneously and was kept down to a maximum of 65° C. by cooling with water. Within an hour a clear solution resulted. After standing over night it set to a firm jelly, which was diluted with acetic acid and separated by means of chloroform. The fine white powder ultimately obtained was soluble in acetone, chloroform, pyridine, hot nitrobenzene, aniline, and slightly soluble in a mixture of alcohol and benzene. Analysis showed it to be a diacetate (C, 48·17, 48·93%; H, 5·66, 5·73%; theory requires C, 48·76%; H, 5·73%). Acetic acid by hydrolysis of an acetone solution (*cf. infra*, the analysis of cellulose acetates), 48·81—48·98%; theory requires 48·8%.

In another experiment 5 g. of filter paper was immersed in 20 c.c. of glacial acetic acid, and 20 c.c. of acetic anhydride containing 0·32 g. of chlorine added, followed by 2 c.c. of acetic anhydride containing 0·26 g. of sulphur dioxide. The mixture rapidly gelatinised, and in less than five minutes solution was complete. After a further five minutes' stirring 20 c.c. of chloroform was added and the ester separated as usual. The product formed fine white flakes of cellulose triacetate (62·4% of acetic acid; theory requires 62·5%). Using the same quantity of cellulose, 20 c.c. of acetic acid, 45 c.c. of acetic anhydride containing 0·066 g. of chlorine and 1 c.c. of anhydride containing 0·069 g. of sulphur dioxide, and warming the mixture slightly, a fine pulp was produced after 10 minutes, which rapidly gelatinised and gave a clear viscid solution from which the ester (acetic acid 64·2%) was isolated.

Preliminary experiments showed that acetylation proceeded best when the weights of chlorine and sulphur dioxide were approximately in the ratio of their molecular weights. This was ascribed to the formation of sulphuryl chloride, and it was therefore considered that by working at its boiling point (69° C.) the reaction would be greatly expedited, since then the sulphuryl chloride would tend to remain gaseous and the escaping bubbles should aid in the rapid clarification of the solution. A mixture of 2 g. of filter paper with 10 c.c. of acetic acid was heated to 69° C., 6 c.c. of acetic anhydride containing 0·28 g. of chlorine added, and then 3·7 c.c. of the anhydride containing 0·25 g. of sulphur dioxide, the temperature being maintained at 69°—70° C. by means of a thermostat.

It is interesting to note that both the acetic acid figures and the values for the recovered cellulose fall off with increase of time of acetylation. The decreasing figures for the cellulose recovered may be taken to indicate some change of the cellulose complex, and although the yields of ester isolated at different stages are the same, this can be explained by the fact that esters from modified cellulose are insoluble in water. The cellulose recovered in the above cases was found to possess the characteristic properties of cellulose, being insoluble in any of the solvents for cellulose acetate and soluble in cuprammonium from which it was reprecipitated by acids.

Cotton wool and bleached and grey American cotton yarn gave similar results to those described for filter paper.

Parallel experiments were made using cotton wool and filter paper. The air-dried samples were immersed in cold diluted Fehling's solution for 30 mins. and washed free from copper solution, and the absorbed copper removed by digestion with dilute acetic acid. The cotton (7·33% moisture) was found to have absorbed 0·83% of copper and the filter paper (5·73% moisture) 0·54% on an air-dry basis (these amounts of copper are proportional to the amounts of cellulose hydrate present. The residual cellulose was boiled with dilute Fehling's solution for 15 mins., the absorbed copper removed, and the products acetylated at 69°—70° C.; the following results were obtained (on an air-dry basis):—

	Cotton.	Filter paper.
Copper, %	1·50 ..	3·92
Residual cellulose, %	92·1 ..	87·4
Yield of ester (total), % ..	170 ..	163

The filter paper cellulose acetylated more vigorously, but the cotton gave a solution of better colour and higher viscosity than the filter paper. After standing for 24 hours a small amount of the cellulose acetate insoluble in acetic acid was precipitated, amounting to 10·6% in the case of the cotton product and 3·9% in the case of the filter paper. These results indicate that the presence of much cellulose hydrate lowers the yield of cellulose triacetate, due no doubt to the formation of soluble products of degradation of the cellulose.

The acetylation of cellulose in presence of a large quantity of water was examined with bleached and with grey American cotton yarns. The absorbed copper due to cellulose hydrate was determined by the action of Fehling's solution in the cold. The wet cellulose was pressed after treatment with the acetic acid and washing with water, and the damp cellulose then acetylated at 65° C. for an hour. Acetylation was more noticeable in the case of the grey cotton. The products were separated by means of chloroform, and the dry products, which retained the fibrous condition, were re-acetylated, giving clear viscous solutions, that from the bleached cotton being superior. The bleached cotton gave 18% of an ester insoluble in chloroform. The following figures show the experimental data:—

—	Bleached.	Grey.
Moisture, %	6·65	7·20
Copper % on dry cellulose	0·33	0·26
First acetylation, yield	103	131
Second acetylation, yield	150	142
Chloroform-soluble portion, C%	48·68	47·60
" " " H%	5·73	5·63
Acetic acid, %	49·6	51·4
Recovered cellulose, %	65·6	51·2

These results appear to indicate that the main ester from the bleached cotton is a diacetate, whereas that from the grey is a mixture of esters approximating to the diacetate.

Note on the analysis of cellulose acetate.

Several methods of hydrolysis of the ester and estimation of the acetic acid by subsequent distillation and titration of the volatile acid, have been suggested. These all possess the disadvantage that the cellulose regenerated by the reaction itself decomposes at the same time, giving rise to volatile acids for which a correction is necessary. It was found that, in the case of acetone-soluble cellulose acetates, the estimation can be greatly simplified. Briefly the method consists in dissolving the weighed cellulose acetate in acetone, hydrolysing the ester in the cold by shaking with a known amount of standard caustic soda in a stoppered flask, allowing to stand for a day, diluting with water, and titrating the excess alkali with standard acid and phenolphthalein. A blank experiment is carried out, using a similar quantity of acetone to which a known weight of cellulose (Swedish filter paper) has been added, and also a blank on a similar volume of acetone. From the two blank estimations a correction for any acidity in the acetone, and also for any decomposition of the cellulose, is made.

The following results with cellulose diacetate give the necessary data:—

Material.	Weight, g.	Acetone, c.c.	$N/10$ NaOH, c.c.	$N/10$ H_2SO_4, c.c.	Acetic acid, %.
Ester	0·3167	30	47·0	18·85	48·98
"	0·3387	30	47·0	17·05	48·81
Cellulose	0·3000	30	47·0	44·20	—
Blank	—	30	47·0	45·90	—

The loss due to the 0·3 g. of cellulose is thus 1·7 c.c. $N/10$ NaOH. Inspection of the amount of

caustic soda neutralised by the ester indicates that the ester is approximately a diacetate, and therefore the regenerated cellulose initially amounted to approximately two-thirds of the weight of ester taken. Hence the number of c.c. of $N/10$ NaOH equivalent to that neutralised by the regenerated cellulose from the first estimation is

$$\tfrac{2}{3}\times(0{\cdot}3167/0{\cdot}30)\times1{\cdot}7=1{\cdot}2 \text{ c.c.}$$

This gives the alkali that is equivalent to the acetic acid as being $45{\cdot}9-18{\cdot}85-1{\cdot}2$ c.c. $N/10$ NaOH = 48·98% acetic acid. Similarly the correction for the cellulose from the second case is found to be 1·3 c.c. This being allowed for gives 48·81% of acetic acid. When the same ester was submitted to alkaline hydrolysis, and the acetic acid determined by distillation, the results were from 43·54 to 44·07%.

In the case of samples of the triacetate the figures will show that the approximate amount of acetic acid is 60%; hence the regenerated cellulose will be about 55%. The correction is therefore based on this and the results worked out as above.

The estimation becomes simpler if the same weight of ester be taken for all estimations, as then the correction to be applied will be uniform.

The ordinary methods of estimation of the acetic acid, which involve distillation and titration of the acid in the distillate, are not accurate enough to detect differences of the order of 1% of acetic acid which are readily indicated by this more exact method.*

My thanks are due to the Department of Scientific and Industrial Research for permission to publish these results, also to Professor Sir W. J. Pope for allowing the investigation to be conducted in the Chemical Laboratory, Cambridge.

* Recent determinations show that even better results are obtained by using 25 c.c. of acetone, $N/1$ alkali, and $N/10$ acid. The correction in this case for the regenerated cellulose is smaller, and for comparative purposes can be neglected.

POSSIBLE DEVELOPMENTS IN HYDROGEN MANUFACTURE.

BY ERIC K. RIDEAL, D.SC., M.A.

The processes now in operation for the manufacture of hydrogen from coal or coke as raw material have centred round the steam-iron process for small scale and the water-gas catalytic process for large manufacturing units. The electrolytic production of hydrogen using coke as the source of power is only economically possible when the hydrogen is formed as a by-product in some electrochemical industry or in special cases where its actual generation and consumption may be confined to interpeak periods on the electrical load.

The Linde-Frank-Caro process of separating hydrogen from water-gas by liquefaction possesses the advantage of delivering hydrogen free from all impurities except carbon monoxide, and conveniently under pressure. The two chief disadvantages of the system are, firstly, the cost of operation and upkeep of the relatively complicated, high-speed machinery involved in the liquefaction plant, which can be partly set off by the proceeds resulting from the installation of an oxygen recovery plant on the liquefier; and, secondly, the high carbon monoxide content (2—4%) of the hydrogen when operating under conditions which will furnish the maximum yield of hydrogen (*i.e.*, 80—85% of the total available in the water-gas). This gas can of course be utilised for many industrial purposes, *e.g.*, for filling balloons or hardening fats, but not in those catalytic processes in which low-temperature hydrogenation is desired, such as in the preparation of the finer hydrogenated oils and hexahydrobenzene, or where the carbon monoxide exhibits a marked inhibiting action, as in the synthesis of ammonia using an iron-base catalyst, or again where it acts specifically as a poison as in the synthesis of ammonia with an irreversible catalyst such as sodamide or uranium carbide. Using a water-gas of average composition (42% CO, 49% H_2, 4% CO_2, 5% N_2 and CH_4) 2·4 volumes would be required to produce one volume of hydrogen. The general utility of the method can only be extended by some effective method for the removal of the carbon monoxide, a point which will be referred to later.

In the steam-iron processes the two representative types are exemplified in the Lane or retort, and the Messerschmidt or block type generators. Under normal conditions these operate between temperatures of 650° and 850° C., and it is interesting to note how far existing practice falls short of the theoretical possibilities of the method. The utilisation of a contact material more reactive than spathose has been suggested in many patents. Such material must be superior to spathose in two respects; firstly, it must operate at a lower temperature, or more rapidly at the same temperature; and, secondly, it must present a larger active surface under operating conditions.

To produce some 2000 cb. ft. per hour of hydrogen 7000 kg. of spathose is required; if complete conversion ($Fe \rightleftharpoons Fe_3O_4$) were effected only 75 kg. would be necessary. The actual yield indicates an output of only 14 cb. ft. of hydrogen per cb. ft. of retort space per make, and a 1% conversion of the spathose. Taking average spathose of 2 in. diameter and mean density 5, the calculated effective conversion depth is of the order of 0·1 mm.; microscopical examination reveals a penetration of 2—3 mm., indicating that but little of the surface is reactive and that the rate of chemical action is consequently partly limited by diffusion of the reactants into the interior. Since a 50% loss on screening after two months operation is by no means uncommon, it is evident that there is considerable room for improvement in this respect. The replacement of the spathose by various forms of activated irons, especially iron-manganese and iron-copper, certainly results in increased yields for short periods, but the enhanced activity at the high temperatures of operation is usually short-lived, owing chiefly to irreversible poisoning during the reducing phase, and loss in catalytic activity due to the thermal treatment which the material undergoes especially in its exothermic phase. At the period of the armistice experiments were being commenced by the Munitions Inventions Board and Department of Explosives Supply to ascertain how far this small surface yield could be increased by an inversion of the process; *i.e.*, instead of passing water-gas and steam over iron oxide, it was attempted to blow finely divided iron oxide through a pipe by means of hot water-gas and transfer the reduced oxide to another pipe, also maintained at suitable temperatures, for oxidation with steam. On paper this scheme presents striking possibilities not only as regards economical utilisation of the spathose—a relatively secondary matter—but also in respect of the size of plant required and the almost certain increase in the activity of the material in this form, permitting lower operation temperatures and an economy in both water-gas and steam. Several types of mechanical devices for the separation of dusts have recently been designed which should provide those interested in the development of such a process with sufficient working data for a suitable design of plant.

The economy of steam and water-gas in the steam-iron process can likewise be examined by comparison

with the theoretical consumption on a basis of unit hydrogen production.

The reactions indicated by the equations,

$$Fe+H_2O \rightleftarrows FeO+H_2;\ 3Fe+4H_2O \rightleftarrows Fe_3O_4+4H_2,$$

have been examined in detail by numerous investigators, notably by Deville (Comptes rend., 1870, **70**, 1105, 1201), Debray (*ibid.*, 1879, **88**, 1341), Preuner (Z. physik. Chem., 1904, **47**, 385), and Chaudron (Comptes rend., 1914, **159**, 237). The various data do not show complete agreement as to the heats of reaction calculated by means of the van't Hoff isochore, but both reactions are strongly exothermic (from 32·1 to 44·1 kg.-cals. per g.-mol.). The heat liberated during the steaming phase can generally be noted on the pyrometer and is entirely lost to the system. The effluent gas will of course consist of steam and hydrogen, and during the complete make the ratio of steam to hydrogen can never fall below the equilibrium values as determined by the above reversible equations; these are 0·176:1 at 440° and 1·0:1·0 at 1500° C. In actual practice, especially towards the end of the steaming phase, a great excess of steam will be present in the effluent gas. Some actual observations on a Lane setting indicated a steam:hydrogen ratio of 1·66:1·0 at the commencement and 6·5:1·0 at the end of a good make, the average being about 3·0:1·0. Thus during the major portion of the make nearly ten times the amount of steam necessary for the reaction was passing through the system, entailing loss both in material and in sensible heat. This loss could doubtless be minimised by fixing a suitable automatic valve on the steam inflow.

The reactions occurring during the reducing phase are much more complicated than those in the steaming phase. Apart from numerous secondary reactions common to both phases, the main reactions on reduction are unknown. It is, however, practically certain that the hydrogen reduces the oxide in accordance with the above equations, but it is as yet uncertain whether the carbon monoxide effects reduction in a similar manner:

$$FeO+CO \rightleftarrows Fe+CO_2;\ Fe_3O_4+4CO \rightleftarrows 3Fe+4CO_2,$$

or whether it operates in a secondary manner due to the intermediate formation of hydrogen according to the well-known water-gas reaction,

$$CO+H_2O \rightleftarrows CO_2+H_2.$$

Although carbon monoxide is a more powerful reducing agent than hydrogen below 850° C., when the equilibrium value constant of the water-gas reaction becomes unity (Henry, Phil. Mag., 1836, **39**, 324; Fay and Seeker, J. Amer. Chem. Soc., 1903, **35**, 641), yet in the absence of moisture it is extremely sluggish. Moisture acts as a catalyst, possibly because the hydrogen formed is a more rapid but less powerful reducing agent than carbon monoxide. An analysis of the spent water-gas from a Lane setting indicated, however, that the water-gas equilibrium was obtained at the operating temperature of 650° C. It is thus possible with the aid of the data on the system hydrogen, water, iron and its oxides, together with those on the water-gas reaction to calculate the theoretical consumption of water-gas during the reducing phase. It may be noted in passing that these data are at variance with those of Baur and Glaessner (Z. physik. Chem., 1903, **43**, 358), Schenck (Ber., 1905, **38**, 2132; 1907, **40**, 1704, and Falcke (Z. Elektrochem., 1906, **22**, 300) on the reactions in blast-furnaces. The cause of the differences is possibly due to the deposition of carbon or the formation of carbides in the blast furnace. The reduction of iron oxide by carbon monoxide appears to be an exothermic reaction at these relatively low temperatures.

The theoretical consumption of water-gas per volume of hydrogen produced has been calculated by Dr. Taylor and the writer, with the following results:—

Cycle $Fe \rightleftarrows Fe_3O_4$

Temperature, °C.	Water-gas consumed. % H_2.	% CO.	Vols. water-gas per vol. hydrogen.
650	30	41	2·85
750	33	40	2·77
850	41	35	2·63

If, on the other hand, the ore does not operate through the cycle $Fe \rightleftarrows Fe_3O_4$ but through the cycle $FeO \rightleftarrows Fe_3O_4$, the consumption of water-gas will be lower, although a smaller yield per kg. of ore will naturally result.

Temperature. °C.	% H_2.	% CO.	Vols. water-gas per vol. hydrogen.
650	42	64	1·8
750	56	70	1·6
850	66	80	1·4

The actual consumption varies between two and three volumes.

The utilisation of the carbon monoxide fraction of the water-gas for reduction purposes has been suggested by several investigators, notably by Jaubert. As has already been indicated, the reaction appears to be exothermic at 650° C., but on the other hand the reaction velocity may be exceedingly low. In addition, precautions have to be taken against the precipitation of carbon on the iron through the secondary reaction $2CO \rightleftarrows C+CO_2$. This latter difficulty can, of course, be readily remedied by application of one of the three general methods which have been suggested. All of these rely upon the maintenance of a suitable ratio of carbon dioxide to carbon monoxide in the reducing gas so as to prevent the precipitation of carbon. According to the data of Boudouard (Ann. Chim. et Phys., 1901, VII., **24**, 5), and Rhead and Wheeler (J. Chem. Soc., 1910, 2179, and 1911, 1141), the ratio carbon dioxide/carbon monoxide is 1·67 at 650° C., 0·72 at 700°, 0·60 at 750°, and 0·07 at 800°. These conditions can easily be produced by operating at very high temperatures, where it will be noted that the ratio sinks to such a small value that the carbon dioxide present in the water-gas or the small quantity produced as it enters the retort is sufficient for the purpose. In general, however, this is not an economical method owing to the short life of the retorts and to the increase in the radiation loss from the bench. The higher CO_2/CO ratio necessary at the lower temperatures can be obtained either by the admission of a little air, as in the block type generator, where partial internal heating obtains, or by the admission of steam during the reducing phase, when an increase in the carbon dioxide content results through the operation of the water-gas reaction. Alternatively the same result may be obtained by passing the mixture of steam and water-gas through a pre-convertor containing catalytic material maintained at a suitable temperature. If more careful investigation supports Jaubert's views as to the merits of carbon monoxide as a reducing agent it would be a comparatively simple matter, provided that due attention be paid to the CO_2/CO ratio, to produce such a gas by the passage of spent water-gas, after removal of the steam by condensation, back through the water-gas generator. Such a gas is clearly much more economically produced than "straight" blue water-gas.

It is evident that with iron oxide as contact material no great improvement over existing practice in water-gas consumption is to be expected, although a marked improvement in steam consumption is theoretically possible. Economy of steam can readily be effected by the employment of activated irons, as is exemplified by the following figures obtained with spiegeleisen (18% Mn) as contact material.

Temp., °C.	Vols. steam per vol. hydrogen in effluent gas.
600	2·0
650	1·8
660	1·6
720	1·25

To reduce the consumption of water-gas involves the utilisation of an oxide more easily reducible than iron; other considerations, such as cost and fusibility of the reduced metal, have apparently militated against the adoption of such materials.

The fuel employed for keeping the retort system hot must also be included on the debit side in hydrogen manufacture. From this point of view the block type of generator is far superior to the retort type, but the hydrogen produced by the former is usually not so pure owing to the difficulties associated with the scavenge. Experiments in Sweden on a typical retort setting of brick and magnesia showed a radiation loss of some 470,000 kg.-cals. per hour. With an average water-gas of 75 kg.-cals. net per cb. ft. a consumption of 6300 cb. ft. per hour would be necessary to make up the deficit. During this period 4000 cb. ft. of hydrogen is produced with an internal consumption of 10,500 cb. ft. of water-gas. The spent water-gas has thus just sufficient fuel value to compensate for the radiation loss, provided that it be burnt in the most economical manner. One proposal for the economical utilisation of heat from the spent water-gas is to effect its combustion by the reduction of some comparatively readily reducible oxide, such as copper oxide, the heat being recovered by re-oxidation of the hot copper with air. By a suitable arrangement of shells in a generator of the block type, it would thus be possible to reduce the iron oxide in one shell and oxidise the copper in another, burning the whole of the water-gas within the unit. The re-oxidation of the reduced copper with air would, however, probably occasion a very great local elevation of the temperature.

The purification of hydrogen from the steam-iron process.

The general methods of purification in use entail merely the removal of the carbon dioxide and hydrogen sulphide.

Sulphur is the most dangerous impurity in hydrogen employed for catalytic purposes; whilst it is customary to remove the hydrogen sulphide from the original water-gas, the organic sulphur compounds such as carbon bisulphide and thiophene remain. Owing to the high percentage of carbon monoxide in the water-gas it would not be feasible to remove this by catalytic decomposition on the surface of hot nickel according the reaction,

$$CS_2+2H_2=C+2H_2S.$$

The quantity of carbon deposited from the carbon monoxide would prove a serious factor in the operation of this (the Carpenter-Evans) process unless the operation were conducted at very high temperatures.

It is well known that in the catalytic water-gas process the sulphur compounds are converted into hydrogen sulphide by hydrolysis at the surface of the catalyst, $CS_2+2H_2O=2H_2S+CO_2$. In the presence of suitable catalytic agents this reaction proceeds much more rapidly than the hydrolysis of carbon monoxide (the water-gas reaction); thus by admitting a small quantity of steam to the water-gas and passing the mixture over a carefully prepared alumina-iron oxide catalyst, the organic sulphur compounds undergo hydrolysis and but little of the carbon monoxide is converted. Precipitated alumina containing suitable quantities of water will actually hydrolyse carbon bisulphide in the cold. The presence of sulphur compounds in the hydrogen is due chiefly to the formation of sulphides during the reduction period; this can most conveniently be obviated by working with a water-gas free from sulphur.

Hydrogen sulphide can also be removed from hydrogen by a process of selective combustion. Iron oxide admixed with certain promoters can be utilised for the oxidation of the hydrogen sulphide at a temperature of about 280° C., according to the reaction $2H_2S+O_2=2H_2O+S_2$. A small quantity of steam must be present to prevent the reduction of the iron oxide. The sulphur is carried forward in the gas stream and sublimes in the colder portions of the tube. The process is, however, complicated by a number of interesting side reactions. If the correct ratio of hydrogen to steam as calculated from the data of Preuner and Chaudron be employed, the following equilibrium is simultaneously obtained: $3S+2H_2O \rightleftharpoons 2H_2S+SO_2$. Although the equilibrium concentrations of hydrogen sulphide and sulphur dioxide at the temperature of operation are small, they are by no means negligible, and as a result an appreciable quantity of flowers of sulphur is deposited with the condensed water in the condenser. In addition, if the catalyst column be long, rehydrogenation of the sulphur vapour occurs, $S_2+2H_2=2H_2S$. This phenomenon is well marked in catalysts containing nickel. Still a third possible method for the removal of hydrogen sulphide is its selective oxidation in a liquid medium, *e.g.* colloidal iron hydroxide, the iron sulphide being regenerated by aeration. Only partial oxidation of the sulphur occurs, the greater bulk being deposited as free sulphur, $2FeS+2H_2O+O_2=2Fe(OH)_2+S_2$.

The sulphides of copper and nickel undergo a similar oxidation, a reaction possibly common to the sulphides of all heavy metals. The reaction velocity at 20° C. varies in a marked manner from metal to metal; nickel is extremely reactive, copper almost inert, and iron of medium activity. It would appear possible that by a suitable choice of metal and the addition of a catalytic oxidation accelerator, *e.g.* a vanadium salt, a reaction velocity comparable with the rate of formation of the sulphide could be obtained. Under these conditions a purely catalytic process for removing sulphide would become operative as distinct from the discontinuous process now in operation in certain coal-gas plants.

For the removal of carbon monoxide there are likewise several alternative schemes which appear capable of industrial development. Of these may be mentioned the method of selective combustion, the process utilising the water-gas reaction, and that of methanation. The methanation process of Sabatier, in which nickel is used as contact agent for the reaction $CO+3H_2=CH_4+H_2O$, proceeds rapidly and smoothly at relatively low temperatures, provided that the hydrogen is free from substances containing sulphur. The method has but small merit for hydrogenating processes in which a circulatory system is in use, for apart from the actual hydrogen consumption—a not unimportant item in a gas containing 2—4% of carbon monoxide—the methane rapidly accumulates in the system, lowering the partial pressure of the hydrogen, unless frequently removed by blowing off.

The utilisation of the water-gas reaction appears much more promising. It has already been indicated that in the steaming phase, 7—10 times the amount of steam actually necessary is passed through the retort system. Since the retort contains iron oxide, it follows that the water-gas equilibrium should be obtained in the effluent hydrogen containing but small quantities of carbon monoxide and dioxide. This was actually found to be the case; the ratio of carbon monoxide to dioxide in the hydrogen was found to conform to the ratio of steam to hydrogen as demanded by theory, the ratio being high at the commencement and very low towards the end of a make. It should thus be

possible to lower the carbon monoxide content of the hydrogen, either by passing the gas as it issues from the retort through another retort in the same bank maintained at a somewhat lower temperature, *e.g.* 450° C., or by mixing the hydrogen from which the carbon dioxide has been removed (or even hydrogen which has already passed through the hydrogenation plant, and is consequently rich in carbon monoxide) with the steam entering the system one or two minutes after the commencement of a make. The following figures indicate the purification which could be effected on an average make of hydrogen containing 0·3% CO and 1·8% CO_2 with these alternative methods.

1. Passage of the make through a catalyst chamber maintained at 450° C. with a hydrogen:steam ratio of 1:3:—Entering gas, 0·3% CO, 1·8% CO_2; effluent gas, 0·07% CO, 2·03% CO_2.

(2) Passage of the hydrogen after removal of the carbon dioxide through the Lane setting two minutes after commencement of the make, when nearly 50% of the make has already been produced: Entering gas, 0·3% CO, 0·0% CO_2; effluent gas, 0·13% CO, 0·9% CO_2. The method of selective combustion involves the removal of the sulphur compounds from the hydrogen. The hydrogen is then mixed with a little more than the requisite amount of oxygen—for very small concentrations of carbon monoxide with twice the theoretical amount for complete combustion—together with a small amount of steam, and passed over suitable catalytic materials such as activated iron or copper oxides. Combustion of the carbon monoxide is complete and a little water is formed. The oxygen is most conveniently generated by electrolysis. This process works admirably on units dealing with 1000 cb. ft. per hour, but has not yet been tested on a larger scale.

The water-gas catalytic process.

It has already been indicated that the minimum water-gas consumption for the steam-iron processes lies in the neighbourhood of 2·5 volumes per volume of hydrogen, and that the steam consumption is at least 4 volumes, which could theoretically be reduced to about 1·5 volumes per volume of hydrogen.

The development of the Mond and Langer catalytic process by the Badische Co. has resulted in the production of 1 vol. of hydrogen by the consumption of 1·2 vols. of water-gas and 2·5—3 vols. of steam. Apart from the problem of the removal of the carbon dioxide, accomplished automatically in the steam-iron processes, it is much more economical than these latter in operation.

The resulting gas has, however, to be freed from some 30% of carbon dioxide and 2—3% of carbon monoxide; this is generally accomplished by pressure-scrubbing with water and then with cuprous salts.

Although the process is more economical than the steam-iron processes, it has not been developed for small-scale work, being in general confined to units so large that the water-gas and steam costs are the sole determining factors. Further investigation on many points is desirable to stimulate more rapid extension of the process.

Water-gas producers for the production of blue gas suitable for direct use in a hydrogen converter will have to be designed. Of the usual 5—6% of inert nitrogen and methane present—sufficient to condemn the hydrogen for many industrial purposes, unless the cost of production were very low—at least half and frequently much more than half is derived from the air and is not due to the presence of nitrogenous substances in the coke. The faulty scavenge after the air-blow is very clearly marked if the nitrogen content of the resulting gas be plotted against the period of the make. Again, although the water-gas reaction is exothermic ($CO+H_2O=CO_2+H_2+10,000$ cal.), the amount of heat liberated is usually insufficient in small units to maintain the system at the usual temperature of operation, 550°—600° C., even with good heat-interchangers and lagging; the loss by radiation is extremely great. This problem would be solved in the most suitable manner by the utilisation of a catalyst operative continuously at 450° C. instead of 550°—600° C. Under these conditions the reaction would be autothermal and a much purer gas would be obtained, since the value of K, the equilibrium constant of the water-gas reaction, sinks from 0·24 at 550° C. to 0·10 at 450° C. With a steam:gas ratio of 2·5:1 the carbon monoxide content would be 3·0% at the higher and 1·17% at the lower temperature. Although many of the activated catalysts will operate on purified water gas at this temperature for reasonable periods, yet up to the present time no one of them has stood the test of operation under industrial conditions.

For small plants alternative methods to pressure scrubbing for the removal of the carbon dioxide and monoxide suggest themselves. Electrolytic regeneration of caustic soda from sodium carbonate would prove a simple but slightly expensive method of operation. By the employment of a divided cell, the electrolytic hydrogen produced could be utilised to augment the main supply. The consumption of water-gas would be about 1200 cb. ft. and of power about 160 kw. per 2000 cb. ft. of hydrogen.

It would be more economical to absorb the carbon dioxide in sodium or potassium carbonate and then to regenerate the bicarbonate,

$$K_2CO_3+CO_2+H_2O\rightleftarrows 2KHCO_3.$$

To effect complete dissociation into the normal carbonate it would be necessary to heat the salt to about 100° C. and to remove the carbon dioxide by vacuum pumping or by spraying in a current of air or steam if the carbonate be in the form of a solution. Absorption would be effected at ordinary temperatures where the partial pressure of the dioxide is very low. The approximate theoretical fuel consumption for decomposition and heating of the bicarbonate to 100° C. is 9700 B.Th.U. per 1000 cb. ft. of scrubbed hydrogen, equivalent to a fuel consumption of only 33 cb. ft. of water-gas. Even if the dissociation process operated with a thermal efficiency of only 10%, this would only entail a consumption of 0·3 vol. of water-gas per volume of hydrogen produced. Where hydrogen is being manufactured for the synthesis of ammonia absorption in ammonia could be employed. The various methods for the removal of carbon monoxide have already been discussed.

The direct production of hydrogen from coke.

The hydrocarbons readily decomposed at low temperatures, such as acetylene or ethylene, are too valuable to be used as a source of hydrogen in competition with the methods already discussed. Other hydrocarbons, such as methane and the paraffins, require such a high temperature for their dissociation as to render their technical utilisation a matter of some difficulty; thus to produce hydrogen containing less than 2·5% of methane a temperature of over 900° C. would be necessary.

The methods based upon the reactions of the water-gas producer are more promising:—

(*i.*) $C+H_2O=CO+H_2$.
(*ii.*) $CO+H_2O\rightleftarrows CO_2+H_2$.
(*iii.*) $C+CO_2\rightleftarrows 2CO$.

For the ultimate conversion of carbon and steam into hydrogen and carbon dioxide by means of these reactions it is necessary to operate at a low temperature. As has already been noted, it is quite possible to arrive at an equilibrium in the water-gas reaction (*ii.*) at temperatures as low as 400° C. with the aid of a catalyst. If some means were at hand for accelerating (*i.*) the most economical solution

of the problem of hydrogen manufacture would be found.

The reaction is heterogeneous and catalytic stimulation is consequently difficult. Several methods for increasing the reaction velocity have, however, been suggested, and some of them have proved feasible on a semi-industrial scale. Thus Harries (J. Gasbeleucht., 1894, 81) utilising a very reactive form of carbon, viz. wood charcoal, obtained equilibrium without the addition of any catalytic material at a temperature of 700° C., but apart from the necessity of employing a special fuel the reaction velocity was found to be exceedingly slow.

Bergius (G.P., 259,030/11, 262,831/12) showed that reactions (*i.*) and (*ii.*) could be accelerated by the simultaneous employment of pressure and a catalyst. He was able to obtain a reaction velocity sufficiently high for technical utilisation at a temperature of 300° C. The pressure was maintained above the critical pressure of water (89 atm.), whilst chlorides, and especially thallium chloride, were employed as catalytic materials. The gas so obtained contained but small traces of hydrocarbons.

Attempts have likewise been made to run the water-gas producer at low temperatures, *e.g.*, 500°—800° C., and to accelerate the reactions (*i.*) and (*ii.*) by the addition of suitable catalytic materials. Haber suggested that the ash, and especially the ashes containing iron, accelerated the water-gas reaction and facilitated the interaction between the carbon and steam, but did not influence the reaction velocity of the interaction between carbon and carbon dioxide. This hypothesis was in part confirmed by Gwosdyz (Z. angew. Chem. 1918, 137), who showed that the reaction velocity of the water-gas reaction was greatly affected by the ash content of the coke. A coke containing 8·5% of ash yielded 29% of carbon dioxide, whilst pure carbon (lampblack, 0·1% ash) yielded only 8·6% of carbon dioxide at 560° C. More recent patents describe the spraying of the coke with suitable catalytic materials before feeding into the water-gas generator. The difficulty associated with the process if the ordinary type of generator be employed would largely depend on the nature of the clinker and the mechanism for its removal. For water-gas generators operating at high temperatures, *e.g.* 1300° C., any increase in constituents forming clinker or fusible slag is to be avoided, but at 600°—700° C. a small increase in clinker content could be permitted. Again the process would appear capable of inversion; powdered coke sprayed with catalytic material could be injected into a current of steam superheated at 700° C., thus obtaining a simultaneous increase in the reaction velocity due to an increase in reacting surface and the elimination of the clinker problem.

Cambridge.

THE ABSORPTION OF ETHYLENE AND PROPYLENE BY SULPHURIC ACID.

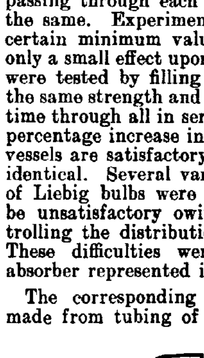
BY SYDNEY GLENN PRESTON PLANT AND NEVIL VINCENT SIDGWICK.

It has been known for a long time that ethylene can be absorbed by sulphuric acid, and this was made the basis for the commercial production of ether by Fritzsche (Chem. Ind., 1898, 21, 27; 1912, 35, 637). The dissociation and decomposition of ethylsulphuric acid at different temperatures has been investigated by Kremann (Monatsh., 1910, 31, 211). The object of the present work was to investigate the effect of varying the conditions upon the rate of absorption of ethylene by sulphuric acid, and also to study the products and the mechanism of the reaction. The ethylene used was prepared by passing the vapour of 97% alcohol over pumice soaked in phosphoric acid and maintained at a temperature of 280°—300° C. The gas was passed from a holder through two wash-bottles containing cold concentrated sulphuric acid, and then through the absorption vessels in series immersed in an oil thermostat. After leaving the last vessel, the gas was passed through another sulphuric acid wash-bottle and collected in a second holder. In this way pressure was applied at the beginning of the series and suction at the end, so that it was possible to maintain a fairly regular stream of gas through as many as five absorption vessels in addition to the wash-bottles for about three hours. The vessels were removed after definite intervals of time, washed with ether and then with water, and finally dried and weighed. The gas was repeatedly analysed by absorbing the ethylene in bromine water, and the volume sent through the vessels during each stage was read off from the graduations on the gas-holder. The gas in the second holder was transferred to the original one and the absorption continued. When not connected up in the series the vessels were kept in the desiccator, the delivery and exit tubes being closed.

The absorption vessel.

Since the experiments were carried out by having an acid of different strength in each of the vessels in the thermostat, it was necessary for the conditions in each to be comparable. By passing the gas at such a rate that the quantity absorbed is small compared with that sent through, the amount passing through each vessel will be approximately the same. Experiments have shown that above a certain minimum value the speed of the gas has only a small effect upon the absorption. The vessels were tested by filling each with sulphuric acid of the same strength and passing the gas for a definite time through all in series, and then calculating the percentage increase in weight of each acid. If the vessels are satisfactory the results would be almost identical. Several variations of the ordinary type of Liebig bulbs were tested, but these proved to be unsatisfactory owing to the difficulty of controlling the distribution of the acid in the bulbs. These difficulties were overcome by using the absorber represented in Fig. 1.

The corresponding parts of each vessel were made from tubing of the same bore, the delivery tube being sealed in a central position with its end as near the bottom as possible. The constriction, A, served to break the bubbles which rose during the passing of the gas, and thereby to check the tendency of the liquid to be carried over into the safety bulbs, BB. The liquid was carried over to a small extent in the final stages of the absorption into the lower bulb, and on a few occasions into the upper one. A small mark, C, was made on the outside of each vessel at a point so as to give as nearly as possible the same amount of liquid in each, and they were filled up to this point for each absorption. Five vessels were made and tested by the method described and found to be satisfactory.



The influence of the speed of the gas upon the absorption.

To investigate this point the gas used in each absorption was taken from a large storage gas-holder, so that the percentage of ethylene in it was constant. It was passed from a graduated bottle of five litres capacity through two wash-bottles containing cold strong sulphuric acid, and then through one absorption vessel containing in every case 99·3% acid and immersed in the thermostat at 70° C. The gas leaving the final wash-bottle was allowed to escape into the outer atmosphere, thereby avoiding changes of pressure which a receiving gas-holder introduces. The pressure driving the gas through the vessel was maintained almost constant by allowing water to siphon from an elevated reservoir into the gas-container, keeping the level of the water in the reservoir carefully regulated. Before each absorption the gas was allowed to bubble for some time through the first two sulphuric acid wash-bottles in order to remove all the air. Before introducing the absorption vessel the gas in the container was brought to atmospheric pressure and its volume read. After each absorption, which was of two hours' duration, the gas in the container was again brought to atmospheric pressure and its volume observed. The following results were obtained:—

Speed of gas in litres per hour.	Increase in weight of acid %
0·60	1·90
0·74	2·09
1·07	2·59
1·54	2·90
2·29	3·07
3·81	3·43

These figures indicate that above 1·7 litres per hour at 70° C. the effect of small variations in the speed of the gas is quite small. This result is quite empirical and will depend upon the nature of the absorption vessel used, since upon this depends the relative amount of liquid surface exposed to the gas and the extent of the stirring.

The effect of the purity of the ethylene upon the rate of absorption.

This was investigated by passing mixtures of ethylene and air of different compositions through 99·3% acid at 70° C. for 2½ hours and observing the percentage increase in weight in each case. The following are the results obtained:—

Ethylene %	Increase %	Ethylene %	Increase %
92·7	3·66	50·7	2·62
86·4	3·87	46·4	2·30
84·0	3·58	41·1	2·21
78·9	3·62	37·3	1·91
72·7	3·58	29·6	1·44
69·6	3·52	25·2	1·32
64·6	3·41	17·9	1·06
59·8	3·14	8·0	0·48
57·3	2·72		

It follows from these figures that above about 69% the percentage of ethylene in the gas has little effect upon the degree of absorption. Confirmation of these results is obtained from the absorption curves.

Analysis of the product of the absorption.

Upon pouring the product of the absorption into water an oil separated at the bottom of the vessel and proved to be diethyl sulphate. Ethylsulphuric acid, some free sulphuric acid, and water are also present in the product. To estimate the amounts of each present the acid liquid was extracted twice by shaking with light petroleum spirit (b.p. 40°—[illegible]0° C.), and the ethylsulphuric acid and diethyl sulphate estimated by oxidation with a standard solution of potassium bichromate (Benedict and Norris, J. Amer. Chem. Soc., 1898, 20, 293). The diethyl sulphate remaining with the petroleum spirit was hydrolysed by heating with water for ½ hour before estimating it. As a rule the difference between the sum of the amounts of ethylene corresponding to each product as found by analysis and the increase in weight of the acids during the absorption did not exceed 2%. The amounts of free sulphuric acid and water present in the product were calculated from a knowledge of the original quantity of acid and its strength. A trace of free alcohol is present in the product as a result of hydrolysis, but will appear as ethylsulphuric acid in the analysis. The actual quantity present is very small, and certainly less than the error (usually about 2%) appertaining to the analytical methods, so that any estimation of it would have been of little value.

The absorption at 50° C.

Three vessels were arranged in series, each containing an acid of different strength, the weakest acid being the first and the strongest the last of the series. The following figures show the percentage increase in weight of the acids based upon the actual (anhydrous) sulphuric acid present. The experiment was conducted in stages of 2–3 hours each, the vessels being weighed at the end of each interval. No appreciable decomposition took place, the acids remaining quite clear throughout, and becoming very slightly brown towards the end.

Time in hours.	Percentage increase in weight. 93·1% acid.	97·6% acid.	99·3% acid.
3	1·24	1·70	2·52
6	2·48	3·57	5·66
9	3·63	5·49	9·38
11	4·82	7·15	12·98
15	6·39	10·90	21·63
18	7·99	14·79	26·78
21	9·68	19·10	29·53
23·5	11·10	22·21	30·99
26	12·51	24·49	32·01
28·5	13·72	26·16	—
31	14·73	27·36	—
33	15·44	28·10	—
35	16·03	28·67	—
37	16·56	29·23	—

These results are plotted as curves in Fig. 2.

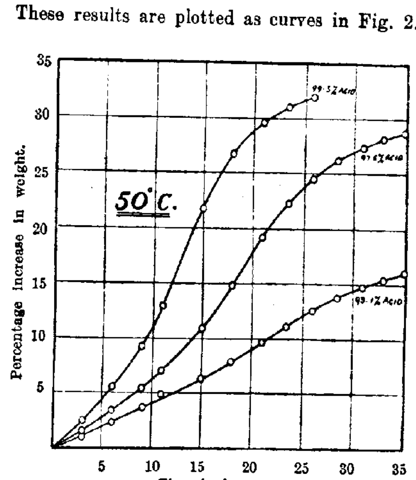


FIG. 2.

The following are the results obtained from the analysis of the products:—

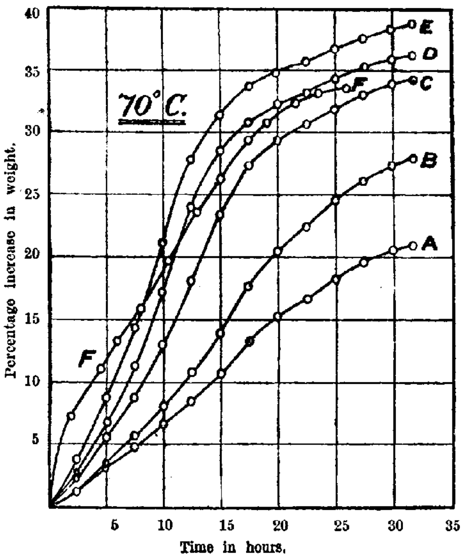
Acid strength.	Increase in weight, %	Ethylsulphuric acid, %	Diethyl sulphate, %	Sulphuric acid, %	Water, %
93·1	16·56	60·1	Nil	33·9	6·0
97·6	29·23	73·9	15·8	8·4	1·9
99·3	32·01	72·7	22·2	4·6	0·5

The absorption at 70° C.

These experiments were carried out in the same manner as those at 50° C., with the following results:—

Time in hours.	93·1% acid.	95·9% acid.	98·1% acid.	98·8% acid.	100·1% acid.
	Percentage increase in weight.				
2·5	1·36	1·28	2·27	2·75	3·83
5	3·16	3·52	5·59	6·82	8·89
7·5	4·78	5·67	8·84	11·32	14·29
10	6·59	8·05	13·06	17·16	21·11
12·5	8·52	10·84	18·11	23·98	27·79
15	10·59	13·95	23·32	28·50	31·46
17·5	13·29	17·78	27·31	30·97	33·64
20	15·22	20.47	29·36	32·37	34·97
22·5	16·56	22·37	30·55	33·20	35·69
25	18·19	24·48	31·95	34·39	36·75
27·5	19·52	26·01	33·04	35·23	37·58
30	20·50	27·30	33·89	35·93	38·24
31·75	20·83	27·98	34·25	36·23	38·62

These results are plotted as curves in Fig. 3.



A. 93·1% acid; B. 85·8%; C. 98·1%; D. 98·8%; E. 100·1%; F. 14% "oleum."

FIG. 3.

There are two small irregularities in each of these curves. The third point in each case, corresponding to 7½ hours, is slightly lower than would be expected from the general direction of the curves; in this case it was found that the ethylene had been passed at too slow a rate. The second and more obvious irregularity is at the ninth point after 22½ hours, which is again too low, but in this case it is due to the fact that the percentage of ethylene in the gas fell to 61·2%. Apart from these two points each curve is quite regular, showing at first a continuous acceleration in the rate of absorption followed by a retardation as the reaction proceeds. The colour of the acid gradually becomes yellow. In no case, however, was there any appreciable decomposition, even with the maximum absorption obtained, all the liquids remaining quite clear. The possibility of the decomposition of the ethylsulphuric acid was investigated by inserting after the absorption vessels a vessel containing about 2 c.c. of $N/10$ iodine solution diluted with water. In no case was there any appreciable decolorisation of the iodine. The absorption was stopped after 31¾ hours, at which point it became difficult to maintain a steady stream of gas through the vessels owing to the large bulk of liquid in them. The volume of liquid increases about 100% during the absorption.

The following table gives the composition of the products obtained:—

I. Acid strength, %	II. Increase, %	III. $C_2H_5.HSO_4$	IV. $(C_2H_5)_2SO_4$	V. H_2SO_4	VI. H_2O
93·1	20·83	69·5	2·2	22·5	5·8
95·8	27·98	79·1	9·4	8·2	3·3
98·1	34·25	74·8	20·3	3·5	1·4
98·8	36·23	68·1	29·3	1·7	0·9
100·1	38·62	70·0	30 0	nil	nil

The absorption at 100° C.

Three of the acids used at 70° (93·1%, 98·1%, and 100·1%) were placed in the same vessels and the absorption investigated in the same manner at 100° C. The following are the figures obtained:—

Time in hours.	93·1% acid.	98·1% acid.	100·1% acid.
	Percentage increase in weight.		
2·5	2·43	5·18	7·43
4	4·34	8·88	11·88
5·5	6·37	13·08	16·67
7·5	8·63	17·11	21·35
9	10·29	20·14	24·52
11	12·39	24·12	28·26
13	14·80	27·02	30·72
15	16·88	28·44	32·08
17	18·69	29·22	32·97
19	19·70	29·34	33·72
21	20·36	29·34	34·00

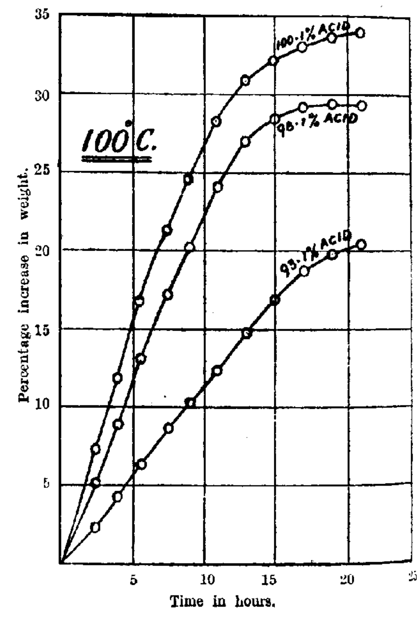


FIG. 4.

These curves (Fig. 4) show the same regularity which characterises those at 70° C. Decomposition of the ethylsulphuric acid is quite marked at 100° C. After running for 1½ hours the strongest acid showed a considerable blackening in colour, and after two hours this was very marked. At the end of 2½ hours the 98·1% acid was brownish yellow and the weakest acid slightly yellow. All the acids were quite black after 11 hours. The question of decomposition has been more fully investigated at 125° C.

The analysis of the products was difficult owing to the decomposition which had taken place interfering with the ease and rapidity of the separation with petroleum spirit. The results obtained were of little value and are omitted.

The absorption at 125° C.

This was investigated mainly for the purpose of observing the effects of the decomposition of ethylsulphuric acid. The gas was more rapidly absorbed at this temperature than at 100° C. until the decomposition of the product retarded the increase in weight and finally made it negative. Only two acids were used, viz.: 93·1% and 100·1%. Both rapidly became black and opaque, and an analysis of the products was impossible. The stronger acid became almost solid from the quantity of carbonaceous material which separated. The following figures were obtained:—

Time in hours.	Percentage increase. 93·1% acid.	100·1% acid.
1·5	2·26	5·41
2·5	3·63	6·92
4	5·53	7·81
5·5	6·46	7·12
7	7·80	6·29
8·5	8·29	4·39
10	7·71	2·65
11·5	6·19	—
13	4·33	—
14·5	2·56	—
16	—0·31	—

The absorption by oleum at 70° C.

The absorption of ethylene by fuming sulphuric :id was investigated by passing the gas through 1% oleum contained in one of the absorption essels at 70° C. The following figures indicate iat the mechanism of the reaction is essentially ifferent from all the other cases:—

Time in hours.	Percent. inc. in weight.	Time in hours.	Percent. inc. in weight.
2	7·47	15	26·25
4·5	11·09	17·5	29·48
6	13·29	19	30·86
8	15·90	21·5	32·56
10·5	19·68	23·5	33·11
13	23·53	26	33·54

From a study of the curve given in Fig. 3 it is t once apparent that the autocatalytic character, rhich is so well marked with the other acids, is bsent. The absorption in the earlier stages is very apid, and this is in all probability due to the comination of the free sulphur trioxide with the gas o give carbyl sulphate, the anhydride of ethionic cid. After a few hours the absorption is proceedng at a rate which corresponds to that which would e observed with about 98% acid, which indicates hat the carbyl sulphate acts merely as a diluent n the same manner as water.

The mechanism of the reaction.

Apart from decomposition there are three successive stages in the absorption, viz.: (1) The solution of ethylene in the liquid, (2) its reaction with sulphuric acid to give ethylsulphuric acid, and (3) its reaction with ethylsulphuric acid to give diethyl sulphate. It is not necessary for all the sulphuric acid to be converted into ethylsulphuric acid before reaction (3) proceeds, as the analyses prove. The theoretical increase in weight for all the acid to be converted into ethylsulphuric acid is 28·57%. At this point, however, a considerable quantity of diethyl sulphate has been formed. The quantity of ethylene actually dissolved as such in the acid being no doubt negligible, the observed increase in weight is a measure of the amounts of reaction (2) and (3) which have taken place. The rate at which the gas was passed was such that a small change in its speed had no appreciable effect upon the absorption, so that the liquid phase must be regarded as saturated with ethylene. These two reactions proceed at rates which are proportional to the products of the concentration of ethylene and the concentrations of sulphuric acid and ethylsulphuric acid respectively.

The curves indicate that the ethylsulphuric acid has a distinct autocatalytic effect, which can also be seen by subtracting each figure from the one succeeding it for any absorption with the exception of those into which decomposition enters. This can be explained by the greater solubility of ethylene in the liquid phase as ethylsulphuric acid accumulates in the system, which is what one would expect. At the end of the experiment, where the rate of absorption is very much diminished, there is still about 70% of the primary product present, so that ethylene must combine with ethylsulphuric acid more slowly than with sulphuric acid.

The amount of diethyl sulphate present at different stages in the absorption.

This question, which has been previously referred to, was more fully investigated by passing the gas through three vessels, each containing 98·1% acid, immersed in series in the thermostat at 70° C. and by taking out the vessels at convenient points in the absorption and analysing the products in the usual manner after observing the percentage increase in weight. The following are the results obtained:—

Increase in weight. %	$(C_2H_5)_2SO_4$ %
25·14	7·9
29·37	14·5
32·42	21·1

Diethyl sulphate begins to appear after about a 20% absorption. The effect of varying the different conditions upon the production of diethyl sulphate can be investigated by a study of the absorption curves together with the corresponding analyses, and a comparison of the results so obtained with this standard curve for 98·1% acid at 70° C. The influence of the water present with the sulphuric acid is found to be small apart from its retarding action upon the absorption in general. The amount of diethyl sulphate present at any given degree of absorption is practically independent of the strength of the acid used.

The absorption of propylene by sulphuric acid.

Experiments have been carried out with propylene on lines similar to those with ethylene. It has been recognised for some considerable time that the former gas was far more readily absorbed by sulphuric acid than the latter. This has been confirmed. It was found that when the gas was passed through 97% sulphuric acid at 25° C. a 50·06% increase in weight occurred after two hours. Absorptions were conducted using acids of strengths between 80% and 90% at 25° C., and the velocities measured were of the same order as those obtained with ethylene and 100% acid at 70° C. The chemical reactions which take place in the case of propylene are far more complex than those between ethylene and sulphuric acid. Apart from the production of propylsulphuric acid and dipropyl sulphate, a colourless oil separated out on the surface of the acid during the course of the absorption. This was separated, washed with an aqueous solution of sodium carbonate, and dried over calcium chloride. The liquid proved to be a mixture, and on distillation under a pressure of 30 mm. the boiling point gradually rose from 55° to 155° C. An investigation showed that this product contained no sulphur, and, furthermore, appeared to consist of saturated compounds. Three fractions were collected on distillation, analyses were made, and various physical constants determined. It was found that some oxygen was present and that the liquid reacted with metallic sodium. It seems probable that the colourless liquid which separates out during the absorption of propylene by sulphuric acid is a mixture of open-chain secondary alcohols. These have probably been produced by propylene

polymerising to give a higher olefine with the double bond in the 1.2-position, having a formula $CH_3.(CH_2)_{12}CH:CH_2$. Sulphuric acid then adds on to the double bond and the compound so produced is hydrolysed to give the corresponding secondary alcohol. The physical constants indicated that the complexity of the molecule was of the order of C_{15}.

PRELIMINARY NOTE ON THE ABSORPTION OF LIGHT BY CAOUTCHOUC.

S. JUDD LEWIS, D.SC., F.I.C., AND B. D. PORRITT, M.SC., F.I.C.

In view of the changes which are produced in rubber when exposed to light and air, it is somewhat surprising that no record appears to exist of any effort having been made to study the action of light on caoutchouc in a quantitative manner. It was therefore decided to carry out some preliminary experiments to determine the character of the absorption of light of short-wave length by caoutchouc, to which experience has shown that the successive physical and chemical changes which occur during "perishing" must be attributed.

With this object a specially good sample of "fine hard Para" rubber was selected in the crude condition before subjection to any manufacturing operation. This was cut into fine strips and submitted to repeated extraction with cold distilled water for a period of over a week, followed by extraction with cold acetone until the washings were no longer coloured. A final prolonged digestion with several changes of absolute alcohol was employed to ensure the complete removal of resins and soluble colouring matters, and the extracted rubber was thereafter dried at ordinary temperature in a current of hydrogen to prevent oxidation. The dry material was then transferred to a stoppered separating funnel in which it was allowed to swell and slowly dissolve in anhydrous ethyl ether (purified by treatment with sodium and fractional distillation) without agitation. The clear caoutchouc solution was withdrawn at intervals before it became unduly viscous, from the bottom tap, the passage of proteid and insoluble matter being prevented by the insertion of a small plug of asbestos fibre, and the volume removed was replaced by the addition of fresh solvent.

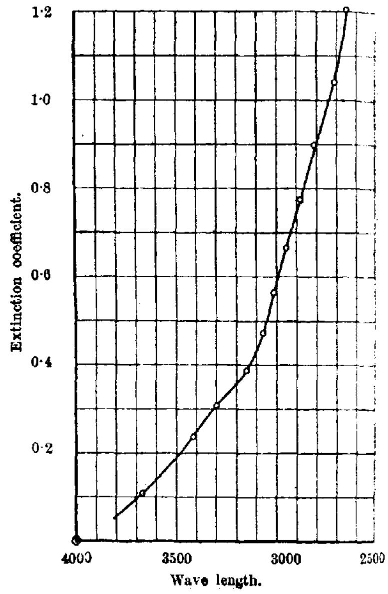
In this way a sufficient quantity of a perfectly transparent, colourless solution of caoutchouc was obtained containing approximately 0·94% of solute by weight. As it was found that this solution gave only very feeble absorption, it was reduced by spontaneous evaporation to about two-thirds of its original volume, thus increasing its strength to approximately 1·5 per cent.

The method of procedure followed was similar to that described elsewhere (Proc. Roy. Soc. B., 89, 329), with the exception of the photometer employed, which was of the new sector type, the details of which have lately been published (Chem. Soc. Trans., 1919, 115, 312).

The 2 cm. cell containing the solution was placed in the one path of light, and a duplicate cell filled with the purified ether, similar to that used for the preparation of the solution, was placed in the other beam for the purpose of providing a control. The absorption effect was therefore confined to the solute alone, that of the solvent being eliminated. The ether employed was found to give no absorption at wave lengths above 2170 sufficient to interfere with the experiment.

The results obtained are exhibited in the accompanying curve, in which are plotted the values of the extinction coefficient, that is of log I/I′, relative to a 3% solution in a cell of unit thickness as ordinates against wave lengths as abscissæ (I is the intensity of the incidental light, and I′ is that of the light transmitted). The curve has not been smoothed out, as the slight irregularities may prove to be significant.

In considering these preliminary results it is in the first place remarkable that caoutchouc should be so transparent to light as to call for the use of so concentrated a solution as 1·5% in a 2 cm. observation tube.



Ultra-violet absorption spectrum curve of ethereal solution of caoutchouc calculated on a 3% solution in a 1 cm. cell.

The curve exhibits only a general absorption which is fairly strong for wave-lengths below 2700, but rapidly diminishes with increase in wave-length.

Neither with the strong solution nor with weaker ones has there been any decisive evidence of absorption bands, but the investigation has not gone far enough to say whether caoutchouc is capable of exhibiting these or not.

Further work is in progress on different types of rubber and allied compounds with a view to confirming these preliminary observations, and if possible securing some evidence regarding the constitution of caoutchouc.

The authors desire to thank the North British Rubber Co., Ltd., for their permission to publish this work, some of which was carried out in their research laboratory.

THE EFFECT OF HEATING LINSEED OIL UNDER PRESSURE AT CONSTANT TEMPERATURE.

BY SAMUEL COFFEY, B.SC. (LOND.).

A considerable amount of work has been published on the properties of linseed oil and the effect of heat, oxidation, etc. The fact that linseed oil lost much of its power of absorbing iodine after heating led Fahrion (Z. angew. Chem., 1892, 5, 171) to suggest that polymerisation had taken place; and this was confirmed by Fokin (Ref. Augsb. Seifens.-Zeit., 34, 821). Later Ingle (J., 1911, 344) found that by heating the oil in a large dish at 195°—200° C. for 43 hours the sp. gr. rose from 0·9315 to)·9800, while the yield of hexabromides fell from 35% to 0·9%, and the iodine value from 180 to 121. Similar results were obtained by R. S. Morrell (J., 1915, 105), who found that linseed oil thickened at 260°—280° contained two modifications, both of which were soluble in light petroleum, but only one n acetone, and approximately equal quantities of he two components were present in the thickened il. The part insoluble in acetone exhibited every vidence of polymerisation, and all traces of linolic nd linolenic acids in the oil had disappeared. The oluble component closely resembled thickened oppy-seed oil, which consists largely of linolic glycerides; the inference as to this is clear. Closely imilar results were obtained by Krumbhaar Chem- Zeit., 1916, 40, 937), who heated the oil for horter periods at higher temperatures. In this ase the sp. gr., viscosity, and acid value inreased while the saponification value remained onstant.

In all these cases, as far as can be ascertained, the il was heated in a more or less non-oxidising tmosphere at atmospheric pressure. Under these conditions a certain amount of volatile products is evolved, and even after seven hours' heating the oil darkens considerably in colour. It has been found, however, that by heating the oil in sealed glass tubes the colour was very much less intense, and the odour of the oil, instead of being somewhat obnoxious, as is the case when linseed oil is heated under ordinary pressure, was pungent but rather pleasant and different from that of the original oil. The author therefore thought it of interest to study the results obtained by heating linseed oil under pressure.

Linseed oil was heated at 250° in sealed tubes which contained very little air, so that oxidation effects and loss of volatile matter were eliminated.

The same sample of "pure" raw oil, direct from he presses, was used throughout the experiments, nd as it was obtained from a reputable firm pecially for the work, it was assumed to be unadulerated, and purification was deemed unnecessary. ts constants were: Sp. gr. at 20° C., 0·9310; aponification value, 189·0; acid value, 6·4; iodine alue, 189·1; hexabromide value, 43·0; glycerol. 0·0%. At the commencement of the experiment even similar tubes containing approximately equal uantities of oil were sealed and heated in a sand ath in an air oven to 250°—260° C.; a similar tube, ut longer, containing the same amount of oil, open the atmosphere, and in which a thermometer was laced, was also inserted in the sand. In no case as the temperature allowed to rise above 260°. The temperature was kept constant for 42 hours, and a tube was removed every seven hours. All the samples of oil were examined together along with the original oil in order to ensure that the conditions for the experiments were identical. All determinations were made at least twice. The oil heated under atmospheric pressure gradually darkened in colour and gave off volatile matter having the characteristic odour of burnt fat, presumably due to acrolein.

The original oil was of a clear golden brown colour, which after seven hours' heating in the sealed tube had changed to a very pale yellow with a slight green fluorescence, which, according to Lewkowitsch, is characteristic of "litho oils" (linseed and tung oils, which have been heated without appreciable oxidation). Further heating appeared to have only a slight effect on colour; even after 42 hours' heating the colour and the fluorescence were not very much more intense than those of the oil heated for seven hours, and in each case the product was paler in colour than the original oil. The specific gravity at 20° C. (determined by the density bottle method) and the relative viscosity at the same temperature (determined by Poiseuille's capillary tube method; original oil=1) are given in Table I.

TABLE I.

Time of heating. hrs.	Sp. gr. at 20° C.	Relative viscosity at 20° C.
0	0·9310	1·00
7	0·9480	2·26
13·5	0·9634	3·52
21	0·9714	4·07
28	0·9723	17·50
35	0·9810	34·40
42	0·9875	49·90

It will be seen that the rise of sp. gr. is practically a linear function of the time during the first 21 hours' heating; it then increases but slightly during the next seven hours, and finally again increases more rapidly, but not so rapidly as at first.

The viscosity rises slowly during the first 21 hours' heating, and then suddenly rises extremely rapidly and practically linearly with time, until after 42 hours' heating it reaches a value 50 times its original value. This most marked break in the continuity of the viscosity curve at 21 hrs. coincides with similar though less distinct breaks in the sp. gr. and acid value curves. It is therefore probable that this stage represents the end or the commencement of some fundamental change in the composition of the oil.

Further qualitative evidence is obtained from a study of the relative solubilities of these oils. In ether and light petroleum, in each case solution was complete, but more solvent was required as the heating continued. In acetone, however, a marked difference was observed. The original oil and the samples which had been heated for 7 and 14 hrs. were miscible with the solvent, but of the oil which had been heated for 21 hrs. a small quantity (about 5%) remained undissolved even after repeated extraction. As the heating continued this insoluble portion became larger; after 28 hrs. it was about 25%, while after 42 hrs. it constituted the larger part of the product. This insoluble product was a thick heavy oil. It is remarkable that the insoluble product should appear after 21 hrs.' heating, at the same time as discontinuities in the viscosity, sp. gr., and acid value curves (*cf. infra*) show themselves, and it seems safe to presume that these marked changes are caused by the production of this thick insoluble product which in all probability is identical with that obtained by R. S. Morrell by thickening the oil at 260°—280° C. (J., 1915, 105, *loc. cit.*)

Chemical properties.—The acid value and saponification values were determined by titration with

alcoholic potash,* the hexabromide value by the Hehner-Mitchell method as used by Ingle (*loc. cit.*), and the iodine value by Wijs' method (Lewkowitsch, "Analysis and Technology of Oils, Fats, and Waxes," p. 240 *et. seq.*). It was found by Morrell (*loc. cit.*) that the iodine values of thickened linseed oil determined by this method increased with the time the thickened oil was in contact with the iodine solution. To eliminate this effect as much as possible the oil was left in contact with the solution for exactly 3 hrs. before titration with standard thiosulphate solution. The results of these determinations are given in Table II.:—

TABLE II.

Time of heating. hrs.	Acid value.	Saponif. value.	Iodine value.	Hexabromide value.
0	6·4	189·0	189·1	43·0
7	10·4	188·2	176·7	mere trace
13·5	11·4	188·3	152·1	—
21	12·6	188·7	142·0	—
28	14·6	189·0	125·2	—
35	15·0	189·0	116·4	—
42	15·0	188·8	107·0	—

These figures show that the saponification value, as in Krumbhaar's experiments (*loc. cit.*), remains unaltered. The iodine values decrease fairly regularly as the heating is continued, the decrease being most rapid at first, but there are no breaks on the curve.

The hexabromide value of 43% in the original oil had become almost zero after 7 hrs.' heating, showing that all traces of the most highly unsaturated glycerides had disappeared, probably owing to polymerisation into glycerides of more saturated diacids, *e.g.*, $COOH{\cdot}C_{17}H_{29}{\cdot}C_{17}H_{28}{\cdot}COOH$ etc. (*Cf.* Morrell, *loc. cit.*)

The acid values are particularly interesting. The original oil had an acid value of 6·4.† On heating, however, the value gradually rose in a continuous manner until after 21 hours' heating. The continuity of the curve is then broken, and the acid value rises abruptly to a constant value from 28 hrs. onwards, equal to about 2·4 times its original value.

It is noteworthy that in these experiments the increase in acid value is not nearly so large as when the oil is heated under atmospheric pressure and volatile matter allowed to escape. In Krumbhaar's experiments, for example, after heating for 20 hrs. at 300° the acid value was 40 times the original, and showed no indication of becoming constant.

No explanation of this pronounced increase in acid value appears to have been put forward. While appreciating the fact that considerably more experimental evidence is required before the point can be settled, the author would suggest that this is due to the direct hydrolysis of the glycerides by water. Raw linseed oil always contains small amounts of water, hence some hydrolysis will take place, and an equilibrium will be set up according to the mass action law as $\{C_{(glyceride)} \times C_{(H_2O)}\} \div \{C_{(glycerol)} \times C_{(acid)}\} = K$ (constant,) and the final acid value for a given oil at constant temperature will be constant as found experimentally. Assuming that K also is small, then for the present case 0·4% of water would be quite sufficient to account for the increase in acid value.

* Some workers consider alcoholic potash to be unsuitable for determining acid values, but the author has found that with neutral alcohol and well kept solutions identical results are obtained with baryta and with potash. It has also been found that acid and saponification values determined by alcoholic potash gave glycerol values identical with those found by the acetin method, although the acid value was as high as 5·3.

† The allowable acid value for linseed oil seems to be somewhat vague; some authorities give it as up to 6 or 7, whilst some say it should not exceed 1 or 2. It should be remembered, however, that in this case a raw oil was used which had undergone no purifying treatment. For four such oils of widely different origin the author has found values of 5·3, 6·4, 5·2, and 3·0—all above 2 but below 7.

In the case of previous experiments, done under ordinary pressures at temperatures about 300°, the glycerol produced by hydrolysis would be volatilised, and so the hydrolysis would go to completion. Also at these temperatures the glycerol would probably be converted into acrolein and water, and so the latter would be continuously formed, and this would account for the high acid values observed.

In conclusion, the author desires to express his thanks to Prof. F. S. Kipping, D.Sc., F.R.S., for his kind interest and encouragement during this work.

THE DETERMINATION OF AROMATIC HYDROCARBONS IN MIXTURES OF HYDROCARBONS.

BY H. T. TIZARD AND A. G. MARSHALL.

In the course of a general research on the behaviour of fuels in internal combustion engines, it became necessary to devise a simple and accurate method for determining the proportion of aromatic hydrocarbons in petrol. The method outlined in this paper is a development of that described by F. B. Thole (J., 1919, 39 T), according to which the mixture is sulphonated with 98% sulphuric acid and the densities before and after sulphonation determined. Thole claims that by the use of 98% acid aromatic compounds are completely removed, while other saturated hydrocarbons are only attacked to a limited extent. He estimates the separate hydrocarbons benzene, toluene, xylene, by fractionating the sample of petrol and dividing the product into three portions: (*a*) b.p. 40°—95°, (*b*) 95°—122°, (*c*) 122°—150° C. It is assumed that (*a*) contains all the benzene and (*b*) all the toluene. The three fractions are then sulphonated separately, and the densities before and after sulphonation determined. The aromatic content is calculated from the difference in densities, making an allowance for the expansion known to occur when aromatic and non-aromatic hydrocarbons are mixed.

Our experiments support Thole's conclusion as to the efficacy of 98% sulphuric acid, and in general confirm the accuracy of his "cutting points," with certain exceptions that will be mentioned later. But the procedure of determining densities before and after sulphonation is open to the great objection that the time involved and care necessary for really accurate density determinations are considerable, and further that the correction to be applied for the divergence of densities of petrols containing aromatic compounds from a simple mixture law is uncertain. Thole's method, too, is only applicable to a very limited extent to the determination of xylene content, since the densities of the three xylenes are different, and it also does not lend itself to a quick and accurate determination of total aromatic content for a similar reason.

The measurement of the critical solution temperature of hydrocarbons in aniline can be used instead of the measurement of density, to determine aromatic content, with greater ease and greater accuracy. Chavanne and Simon, who have worked on similar lines, have recently pointed out (Comptes rend., 1919, 168, 1111, 1324; 169, 185, 285) that paraffin, naphthene, and aromatic hydrocarbons are very distinctly differentiated by the temperatures above which they are completely miscible with aniline. This temperature for paraffins is high (about 70° C.), for naphthenes about 30°—50° C., while aromatic hydrocarbons are

miscible down to very low temperatures. The addition of aromatic compounds to paraffin and naphthene hydrocarbons lowers this critical solution temperature by an amount very nearly proportional to the concentration of aromatic hydro-carbon present. The curves in Fig. 1 show results of experiments made in this laboratory on the solubility in aniline of a "petrol" freed from aromatic hydrocarbons, and the same mixed with different amounts of benzene, up to 39% by weight. The curves show the temperatures above which mixtures of aniline and the "petrol," represented in composition by the abscissæ, become homogeneous. When cooled to temperatures represented by points below the curves separation into two layers occurs. The critical solution temperature in each case is represented by the maximum point; above this point mixtures in all proportions of the respective petrol and aniline are homogeneous.

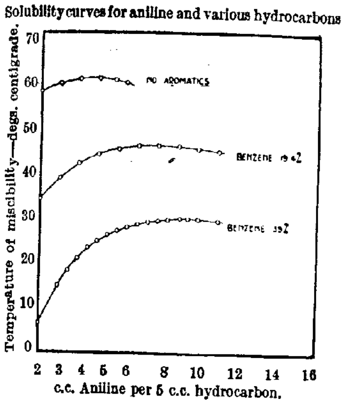

FIG 1.

The most important feature of these curves is that the proportion of aniline and hydrocarbon at the critical point varies from approximately equal volumes when no aromatic hydrocarbons are present to about 9 volumes of aniline to 5 of "petrol" when the latter contains about 40% of aromatics.

Now, Chavanne and Simon always determine the critical solution temperature, *i.e.*, the temperature represented by the maximum points of the curves in Fig. 1. When this method is used to determine aromatic hydrocarbons it involves following out two such curves, one before and one after sulphonation in every case. This is obviously unpractical, and tends to make the method as laborious as that of the accurate determination of densities. This was recognised at an early stage of the present investigation, and it was decided to measure in every case not the true critical solution temperature, but the temperature of solution of equal volumes of aniline and the hydrocarbon. In practice this comes to the determination of the point of separation into two layers of the "equal" mixture, when it is gradually cooled down from a temperature at which it is homogeneous. This temperature is called by us the "aniline point"; it can be determined with considerable accuracy—certainly to within 0·1° C. with a little practice. In the case of mixtures containing a very small percentage of aromatic hydrocarbons the aniline point corresponds to the true critical solution temperature within 0·1° C., but when a high percentage of aromatic hydrocarbons is present it may be quite considerably different. In the first case it is obvious from the curves that any possible error in the volumes of aniline and petrol taken causes only a negligible error in the temperature observed; in the second case it can also be shown that the error is inconsiderable. When the aromatic content is as high as 39%, a 2% error in volume measurement only makes a difference of 0·3° in the "aniline point," which corresponds in this case to 0·3% of aromatic hydrocarbons, *i.e.*, the error in such an event would be less than 1% of the total aromatic hydrocarbons present. This is an outside estimate of the possible error due to this cause; by always using the same pipettes in measuring out the aniline and the hydrocarbon respectively the volume error is very unlikely to be as much as 2%.

The actual critical solution temperature of aniline and the 39% benzene mixture was found to be rather ill-defined, and it was difficult to get consistent readings to 0·1°, while the "aniline point," *i.e.*, the temperature of separation of equal volumes, was very sharply defined, and could be very accurately determined.

The actual determination of the aniline point is made most conveniently by measuring out from pipettes, 10 c.c. each of aniline and the hydrocarbon into a large test-tube, fitted with a stirrer and a delicate thermometer (reading in 0·2° to 0·1° C.), heating until a clear solution is obtained, then cooling slowly and noting the temperature at which turbidity appears. The mixture is then warmed again very slightly until it is just clear, and the point of turbidity redetermined on cooling. It is necessary to repeat this once or twice in accurate determinations in order to eliminate any error due to possible lag of the thermometer. It is found that a very slight turbidity first appears, and then the mixture suddenly becomes completely cloudy, the thermometer bulb being obscured over a range of about 0·1°. The temperature at which this complete turbidity occurs is taken as the aniline point.

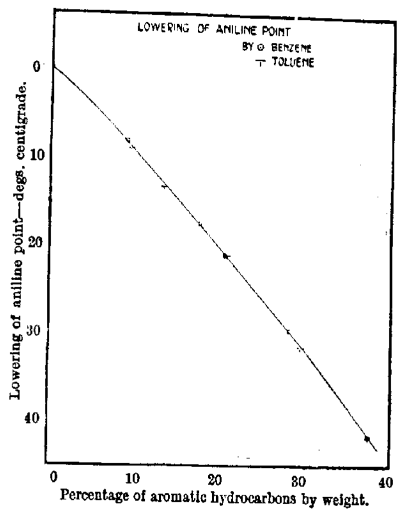

FIG 2.

The means of heating is a naked flame. When the aniline point is more than 10° above room temperature, the experimental tube is surrounded by a larger tube, so as to leave an air space between the tubes, which ensures that warming and cooling take place gradually. When the aniline point is below room temperature, the tube can be cooled in ice and water, or a freezing mixture. More conveniently the cooling can be accomplished by placing ether in the larger external tube, through which air can be drawn. The apparatus is thus of the greatest simplicity, and from this point of view alone the method has great advantages over those

depending on the measurement of other physical properties such as refractive index or density.

There is further the very considerable advantage, shown during the course of this investigation, that benzene, toluene, and xylene appear to have practically the same effect in lowering the aniline point when added to any mixture of hydrocarbons in the same proportion by weight. Figs. 2 and 3 show the results of special experiments made to find out the effects of the different aromatic hydrocarbons. For these experiments, benzene, toluene, and *o*-, *m*-, and *p*-xylene, were obtained in as pure a state as possible, and the aniline points were determined of special mixtures made up by weight of

(*a*) Benzene and toluene with a mixture from which all aromatic hydrocarbons had previously been removed by sulphonation (Fig. 2).

(*b*) The different xylenes with a similar mixture of higher boiling point. In this case also two check mixtures were made up containing benzene and toluene respectively (Fig. 3).

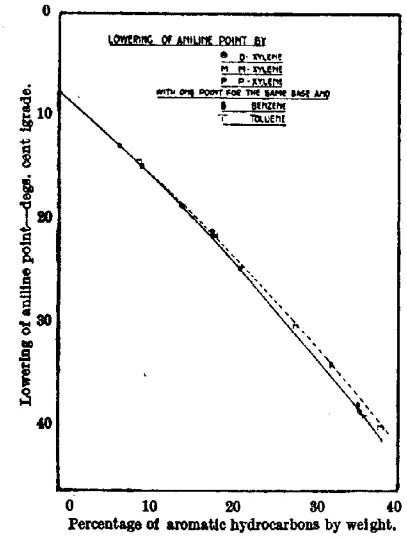

FIG. 3.

Benzene, toluene, and *o*-xylene were found to have identical effects within the errors of experiment, while *m*- and *p*-xylenes lowered the aniline point rather less than the same weight of benzene or toluene. But for all practical purposes it is safe to assume that the same proportions of these hydrocarbons by weight have the same effect in lowering the aniline point, and the following table, from the figures of which Fig. 2 has been constructed, gives the relation between the lowering of the aniline point of a mixture containing no aromatic hydrocarbons and the amount of aromatic hydrocarbon added:—

Percentage of aromatic hydrocarbon in mixture.		Lowering of aniline point.
5% by weight.	..	4·2° C.
10 ..	..	8·6
15 ..	..	13·2
20 ..	..	18·1
25 ..	..	23·2
30 ..	..	28·5
35 ..	..	34·0
40 ..	..	39·8

The total aromatic content of any petrol can therefore be determined by this method with considerable accuracy.

The procedure is to determine the aniline point of the petrol, then to shake for ½ hr. 30—50 c.c. of the petrol with three times its volume of 98% sulphuric acid, allow to stand, separate the acid, wash the residue with sodium hydroxide solution and water, and dry over calcium chloride. The aniline point of the residue is then determined. The difference between this and the aniline point before sulphonation gives directly the percentage of aromatic hydrocarbons in the mixture. The accuracy has been tested in two cases by making up artificial mixtures by adding known weights of benzene, toluene, and xylenes to a sample from which all aromatic hydrocarbons had previously been removed. The results were:—

	Case I.		Case II.
Percentage by weight of benzene added	12·4	..	2·3
" " " toluene "	14·5	..	16·5
" " " xylenes "	11·3	..	3·0
Total	38·2	..	21·8
Total found by aniline point method ..	38·6	..	21·8

If the whole of the added aromatic portion had been *m*-xylene, the error caused by assuming that this hydrocarbon had the same effect as benzene and toluene would be not more than 3% of the total weight added, but naturally this is a circumstance not likely to occur in practice.

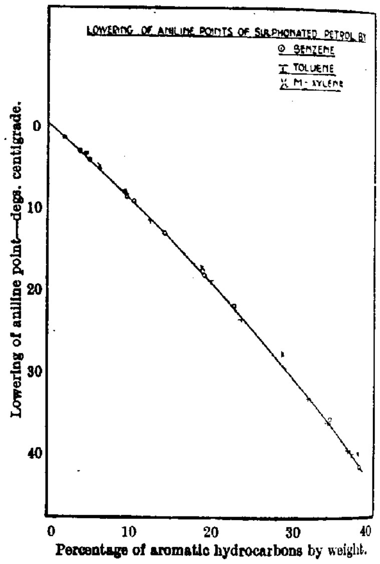

FIG. 4.

The curve is the same as Fig. 2, but the bases used vary widely.

It has been found that when extreme accuracy is not desired the processes of washing and drying the mixture after sulphonation can be omitted. The estimation is then extremely simple, for it is only necessary to pipette off 10 c.c. from the supernatant liquid after sulphonation, and to determine its aniline point immediately. The temperature of turbidity does not differ by more than 0·2° from that of the washed and dried mixture, and the time saved is very considerable.

The above example incidentally gives a proof of the completeness of the removal of aromatic hydrocarbons by shaking with excess of 98% sulphuric acid for ½ hr. In general our experiments have confirmed Thole's conclusion that the use of acid of this strength prevents action on other hydrocarbons. Very little sulphur dioxide is evolved, and the mixture only gets warm on shaking when there is a large proportion, say 40%, of aromatic hydrocarbons. It is possible that the use of even more dilute acid would be advantageous for analytical purposes, but it has not been thought

worth while to examine this question at present. A special experiment during the sulphonation of a mixture containing 10% of aromatic hydrocarbons showed that nearly all the latter were removed in the first 2½ minutes of shaking.

In another case, when it appeared likely that the non-aromatic portion was attacked by the acid, the residue after the first sulphonation was again shaken with fresh acid. There were undoubtedly signs of a further reaction, but the aniline point after this treatment was found to be unchanged, showing that such action as occurred did not affect the accuracy of the method for determining aromatic hydrocarbons.

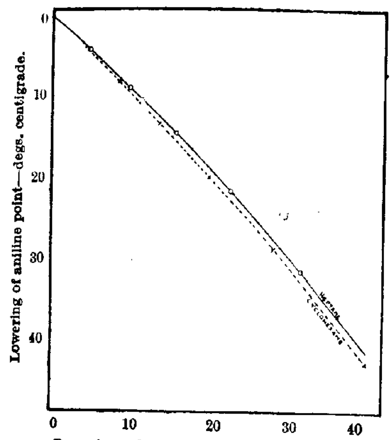

FIG. 5.

Lowering of aniline point of $\left\{\begin{matrix}\text{heptane}\\\text{cyclohexane}\end{matrix}\right\}$ by benzene.

The next question of practical importance that arises is to what extent the lowering caused by a given weight of aromatic hydrocarbon depends on the nature of the non-aromatic base. Is the lowering, for example, the same when the base is cyclohexane, which has an aniline point of about 30° C., as it is with a pure paraffin such as heptane, which has an aniline point above 70° C.? This would certainly not be expected, and special experiments, made with mixtures of pure specimens of these hydrocarbons with benzene, have shown that it is not the case. The results of these experiments are shown in Fig. 5, the lowering in the case of heptane being less than it is when the non-aromatic base is cyclohexane. The standard curve lies between these two, and the difference between the two curves corresponds to a difference of about 3% of the weight of aromatic hydrocarbons added. But although the nature of the non-aromatic base does affect the degree of lowering, the effect is generally too small to be of practical importance. This is shown more clearly in Fig. 4. In this figure the standard curve of Fig. 2 is reproduced, and the experimental points shown represent results obtained with all the different "natural" petrols so far examined. These petrols range from a Borneo product which has the highest proportion of naphthenes, to American petrol which has the lowest. The aniline points of these fuels after removal of aromatic hydrocarbons vary from 54° C. in the case of former to 64° C. in the case of latter. All the points lie on the same curve within the experimental errors, except those taken with *m*-xylene, to which reference has already been made. It appears, therefore, that in practice the nature of the non-aromatic base has a negligible effect, and the figures given in Table I. may be taken as standard figures for all natural "petrols."

At the same time, if any doubt exists as to this a check on the accuracy of the determination can easily be obtained in the following way. After the aniline point of the sulphonated residue has been measured, the percentage of aromatic hydrocarbons is calculated approximately from the data given in Table I. (or Curve 2). A solution containing approximately the same weight of benzene, or, better still, two solutions, one containing slightly less, and one slightly more than the calculated result, are made up by adding known weights of benzene to the sulphonated base. The aniline points of these artificial mixtures are determined, and the true aromatic content of the original petrol can be obtained by a very slight interpolation. This procedure is often of value when the non-aromatic base contains a large proportion of low-boiling fractions and has a high aniline point. An actual example will make the method clear. The aniline point of mixture before sulphonation was 36·8° C., and after sulphonation 62·7°. During the latter determination some boiling was observed. A difference of 25·9° C. corresponds to 27·6% of aromatic hydrocarbons from the standard curve. A mixture of the sulphonated product and benzene was then weighed out, containing 28·09% of benzene. The aniline point of this solution was 36·6° C. From the standard curve it is found that when the aromatic content is 28% a difference of 0·2 in the aniline point corresponds to a difference of 0·19 in the aromatic content. Hence this is the correction to be made to ascertain the true percentage of aromatic in the original petrol, which is

$$28{\cdot}09 - 0{\cdot}19 = 27{\cdot}9\%.$$

In all the above experiments freshly distilled aniline was used. Commercially "pure" aniline contains small quantities of aminothiophene, the presence of which accelerates oxidation when the aniline is exposed to air and light. In order to ascertain the effect of impure aniline on the aniline point method, moist air was bubbled through aniline for six hours. Experiments made with this product showed a rise of no less than 10° C. in the true "aniline point" of a hydrocarbon base containing no aromatic hydrocarbons. So far as the accuracy of the method for determining aromatic hydrocarbons goes this would be of no consequence if the "lowering" due to addition of aromatic hydrocarbons were the same, but this is not the case.

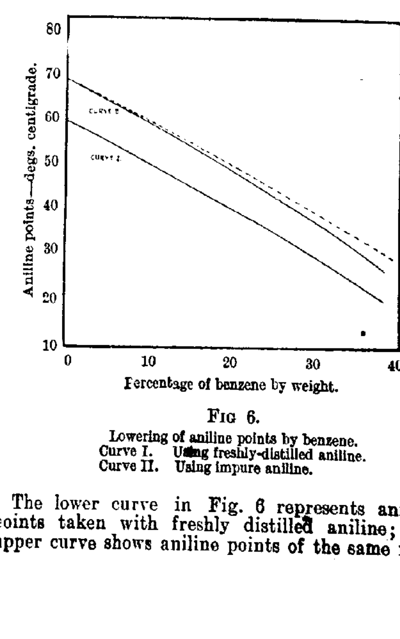

FIG 6.

Lowering of aniline points by benzene.
Curve I. Using freshly-distilled aniline.
Curve II. Using impure aniline.

The lower curve in Fig. 6 represents aniline points taken with freshly distilled aniline; the upper curve shows aniline points of the same mix-

tures with impure aniline. The dotted line has been drawn parallel to the lower curve, and is seen to be of a different slope to the upper continuous curve. Care should therefore be taken to use fairly freshly distilled aniline, but it may be pointed out that all disturbing factors of this kind are eliminated by using the more accurate method outlined above. It would probably be advantageous to use aniline, freed from aminothiophene, or, alternatively, prepared from benzene free from thiophene.

It is important to notice that the purity of the aniline employed seriously affects any analytical methods which depend on the knowledge of absolute aniline points. Chavanne and Simon use the critical solution temperature in aniline to differentiate between naphthene and paraffins etc., and to determine the proportions of such hydrocarbons in petrol. But, owing to the above and other difficulties, an estimation made in this way is only very approximate, although it is often of value to use the method in combination with the density method.

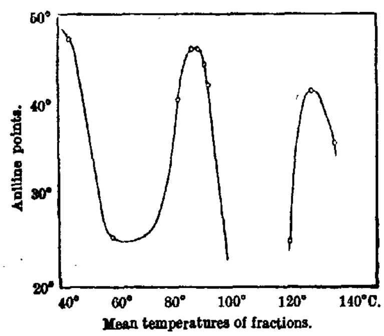

FIG. 7.
Cutting point curve.

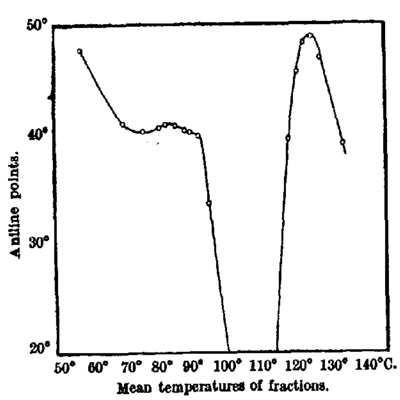

FIG. 8.
Cutting point curve.

The extension of the aniline point method to the determination of the individual aromatic hydrocarbons involves a separation of the sample by fractionation into fractions containing the benzene, toluene, and xylenes, etc., and separate sulphonation of each of the fractions. In spite of the considerable differences in the boiling points of these aromatic hydrocarbons (benzene 80·4°, toluene 110·3°, xylenes about 139°), it is well known that even when a very efficient fractionating column is used, they distil over wide ranges of temperature. Thole recommends "cutting points" about half way between the boiling points. He assumes that the fraction distilling over up to 95° contains all the benzene, that between 95° and 122° all the toluene, and that from 122° to 150° all the xylenes. Probably this is not true, but it is reasonable to assume that any benzene distilling over above 95° is balanced by an approximately equal amount of toluene distilling over below 95°. If the densities of the successive fractions are determined it is found that maximum densities occur at about 80°, 110°, and 140°, and minima at about 95° and 122° C. If the aniline points of the successive fractions are determined it is found that maximum points occur near the latter temperatures, indicating that the percentage of aromatic hydrocarbons in the distillates coming over at these temperatures passes through a minimum. It is naturally much quicker to determine aniline points, and if it is considered desirable to ascertain the "cutting points" for any particular fuel as accurately as possible, the petrol is fractionated, and the aniline points of small fractions coming over within small ranges of temperature near 95° etc. are determined. The temperatures at which the aniline points pass through maximum values are taken as the correct cutting points, and a separate fractionation then made.

The following were the results obtained with the two "artificial" petrols referred to above (Case I. and Case II.). In Case I., in which the proportions of benzene, toluene, and xylene were approximately equal, the cutting points found were 95° and 124° C. (see Fig. 7). Sulphonation of the separate fractions and determination of aniline points as described above gave the following results:—

	Found.	Correct value.
	%	%
Benzene	12·5 ..	12·4
Toluene	14·4 ..	14·5
Xylene	10·6 ..	11·3

In Case II. the proportion of toluene was purposely made high compared with that of benzene and xylene. The aniline points of the successive fractions are shown in Fig. 8, from which it is seen that the maxima occur at 90° and 125° C. Analysis of the fractions obtained by cutting at these temperatures gave:—

	Found.	Correct value.
	%	%
Benzene	2·4 ..	2·3
Toluene	16·7 ..	16·5
Xylene	2·3 ..	3·0

The agreement for benzene and toluene is very good in both cases. The xylene found is a little too low. This may be partly attributed to some uncertainty in the purity of the xylene taken to make up the mixtures, but probably mainly to the fact that the xylene fraction was only one-fifth of the whole in the first case, and one-seventh in the last. It partly consists of the liquid obtained by draining the fractionating column and condenser, and any loss due to incomplete drainage tends to make the xylene value rather too low.

The errors that would have been caused by taking the normal cutting points of 95° and 122°, instead of 90° and 125° may be estimated in the following way.

Between 90° and 95°, 40 c.c. distilled over, containing about 10% of aromatic hydrocarbons. The total amount of the product distilled was 500 c.c., so that this represented

$$\frac{1}{10} \times \frac{40}{500} = 0{\cdot}8\ \%$$

of aromatics in the total. If this had been included in the benzene fraction it would have raised the benzene value to 2·4+0·8=3·2%, whereas the actual benzene content was 2·3%.

On the other hand only 8 c.c. distilled between 122° and 125°, and the distillate contained 8%

aromatics. Had this been included in the xylene fraction, it would have raised the percentage of xylene by 8×8+500=0·13, and the final values would have been benzene 3·2%, toluene 15·8%, xylene 2·4%. Hence in extreme cases, when the aromatic content consists mainly of one hydrocarbon, the error due to assuming the correct cutting points to be 95° and 122°, without making a special determination, may be fairly considerable, but for all ordinary cases these cutting points are sufficiently accurate.

In conclusion, to show the degree of agreement found in actual analyses between the total aromatic content, and the sum of the individual hydrocarbons, the experimental figures for a number of products examined in this laboratory are quoted:—

Fuel.	Benzene. %	Toluene. %	Xylene and higher aromatics. %	Total. %	Total found independently. %
(1)	6·1	16·3	16·7	39·1	38·0
(2)	7·2	17·5	10·3	35·0	35·2
(3)	5·6	8·0	1·3	14·9	14·6
(4)	4·9	4·1	0·9	9·9	10·0
(5)	0·7	3·8	3·8	8·3	8·6
(6)	2·7	4·4	1·8	8·9	8·4
(7)	2·7	4·9	2·2	9·8	10·1
(8)	1·0	1·8	1·4	4·2	4·4

It should be remembered that as outlined above this method is only applicable to the estimation of aromatic hydrocarbons in mixtures which contain negligible quantities of unsaturated hydrocarbons. The presence of the latter introduces a serious complication, which will be dealt with in a later paper. The method has now been in use for some time with satisfactory results in the laboratories of the Asiatic Petroleum Company, to the directors of which we are indebted for permission to publish the above results.

Organic Chemical Laboratory, Oxford.

SOLUTIONS OF ACETYLENE IN ACETONE AT HIGH PRESSURES.

BY RAYMOND R. BUTLER, B.SC., A.I.C.

In the course of experiments in connexion with the solution of acetylene in acetone at high pressures, it became necessary to obtain a knowledge of the rate of expansion of a given volume of acetone when saturated with acetylene at pressures in the neighbourhood of 10 atmospheres.

An examination of the literature on the subject revealed a remarkable dearth of information.

Claude and Hess (Comptes rend., 124, 626) showed that the increase of solubility of the gas in acetone is nearly proportional to the pressure. This is the basis upon which the dissolved acetylene industry was founded. They also showed that when saturated at a pressure of 1 atm. the acetone increased in volume by about 4%.

Siller ("Versuche über gelöstes Acetylen," 1913) found that the expansion factor was 4·7% up to a pressure of 75 lb. per sq. in.; no investigation was made at higher pressures.

It was therefore decided to investigate the nature of the solution at higher pressures, and in view of the danger attending the compression of the acetylene at pressures greater than 2 atm. specially designed apparatus was necessary.

Method of storage of gas.

Since gas containing acetone vapour, as delivered from cylinders of dissolved acetylene, was useless for our purpose, the gas was stored in a cylinder of 2 cub. ft. capacity filled with beech charcoal, of Belgian manufacture, of absolue sp. gr. 1·41.

It was desired to obtain a porosity of about 80% in the gas storage cylinder, the water capacity of which was 124 lb. 10 oz. weight of water. It was therefore necessary to fill the cylinder with 35 lb. 3 oz. of charcoal. The cylinder so prepared was completely exhausted of air and occluded gases by subjecting it to a hot vacuum process at 100° C. for 24 hours. It was then cooled, and when cool filled with acetylene by means of a compressor.

The acetylene used was obtained from calcium carbide in a carbide-to-water generator, from which it passed through a hydraulic main, purifiers containing chromic acid mixture, and dust traps, previous to entering the compressor.

The gas was allowed to enter the cylinder from the compressor slowly in order to avoid local overheating, with consequent danger of explosion. Acetylene compressed at a pressure greater than 2 atm. is liable to decompose with violence unless absorbed in a porous mass the interstices of which have an average diameter of less than 0·5 mm. (Le Chatelier).

On disconnecting from the compressor, and cooling, the cylinder was found to contain gas at a pressure of 175 lb. per sq. in.

Absorption apparatus.

The apparatus used for the absorption experiments is illustrated in Fig. 1. It consists of a constant temperature bath, F, through which a steady stream of water flowed from a thermally-regulated constant-temperature cistern; an inner glass pressure tube, B (34 in. in length, approx. diam. ¾ in.), held by means of tie-rods, H, between metal plates, G, G, and making a gas-tight joint with each plate by means of a fibre seating (see Fig. 2); an outer steel safety tube, C, surrounding B, and having a narrow slit running from end to end, through which the level of the acetone could be observed, and its height obtained accurately on a metal scale (not shown).

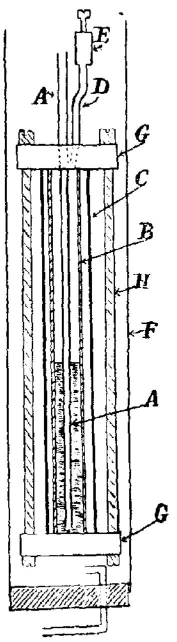

Fig. 1.

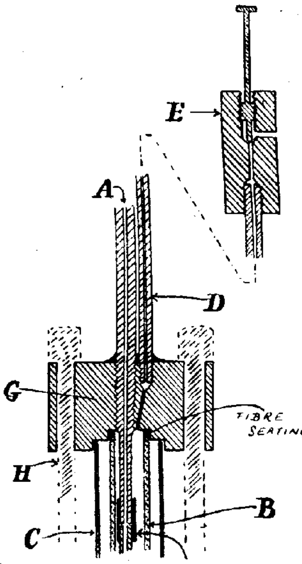
Since it is impossible to obtain acetylene of 100% purity by any ordinary method, the gases other than acetylene (which are but slightly soluble in acetone) were allowed to escape by means of the gas outlet valve, E, which served as the fine-adjustment valve for each high pressure reading.

The compressed gas from the storage cylinder was admitted by way of a standard pressure gauge into A, whence it bubbled up through 20 c.c. of acetone in B, collecting in the space above the acetone and establishing the necessary pressure on the surface. When the gas passed through without dissolving (this was readily indicated by the bubbles) the excess of gas was allowed to escape slowly through E.

The pressures were then finally adjusted by means of E so that the state of balanced pressures was obtained, and the acetone rose inside A. Each reading was taken under the same conditions, the

height being read when the level of the acetone inside A was identical with that of the main bulk of acetone surrounding A. Great care was necessary in the final adjustments made by the valve, E, as it was found that any slight irregularity in the glass below the surface of the acetone had a tendency to form a centre from which bubbles of dissolved gas attempted to escape from solution.



Rubber connexion between metal and glass.

FIG. 2.

The acetone used had b.p. 56·5° C.; sp. gr. 0·794 at 15° C., coefficient of acetylene absorption, 23·8 volumes at 15° C.

The readings were taken at 15·8° C. It was found by experiment that 1 cm. height of acetone in inner tube B=0·472 c.c. The following results were obtained:—

Absolute pressure, lb. per sq. in.	Scale reading, in cm.	Increase in length, in cm.	Expansion in c.c.	Increase in volume. %
0	40·8	—	—	—
15	42·5	1·7	0·80	4·0
30	44·6	3·8	1·80	9·0
45	46·4	5·6	2·64	13·2
60	48·4	7·6	3·60	18·0
75	50·0	9·2	4·34	21·7
99	52·7	11·9	5·62	28·1
125	56·4	15·6	7·36	36·8
145	58·8	18·0	8·50	42·5

The above results when plotted on a curve, with pressures as abscissæ, and expansions as ordinates, show that up to a pressure of 10 atm. (absolute) the expansion follows a straight-line law, the percentage expansion per atmosphere increase in pressure being 4·4%.

This figure is important, in view of the Home Office order permitting the filling of dissolved acetylene cylinders to a pressure of 15 atm. It is obvious that under these conditions the acetone in the cylinder may expand by as much as 64% of its original volume.

In a cylinder containing 40% of its volume of acetone, the final volume of the acetone, calculated from this factor, is 65·6% of the volume of the cylinder. In addition, an ordinary dissolved acetylene cylinder, filled with porous material having a porosity of 80%, has a total volume of solid matter within it of 20% of its volume. The total free space actually existing in the charged cylinder is thus only 14·4%.

This figure must be still further reduced should the acetone expand, due to any pronounced increase of temperature of the cylinder and contents.

There is no evidence that any compound is formed between the solvent and the solute. Up to a pressure of 10 atm. absolute the phenomenon appears to be entirely physical in nature.

These results were obtained in the course of a series of experiments carried out in the laboratories of the Dissolved Acetylene Company, London, S.W. 8.

NOTE ON THE RATE OF REACTION OF PICRIC ACID WITH NITRATING ACID.

BY D. L. HAMMICK.

During the course of some experiments on the yields of picric acid obtainable by carrying out the nitration of phenol at higher temperatures than are usual, it became necessary to ascertain the rate of reaction between picric acid and the nitrating acid. The following experiments were therefore carried out.

A nitrating acid was made up of equal parts by weight of water, nitric acid (68%), and sulphuric acid (sp. gr. 1·345). Pure, recrystallised picric acid was dissolved in excess of this mixture and heated in a 250-c.c. Kjeldahl flask in a constant temperature oil bath. Loss of water and nitric acid by evaporation was prevented by the insertion of a close-fitting glass condenser into the neck of the flask. Portions of the picric acid solution were removed from time to time, diluted, extracted with ether, and the extract evaporated and dried at 100° C. The residual picric acid was then estimated with titanous chloride by Knecht and Hibbert's method.

The results obtained are given below. The initial concentration, a, of the picric acid is in grams per 100 c.c. of solution; $a—x$ is grams picric acid in 100 c.c. of solution after time T (in days). K is the unimolecular velocity constant in the equation.

$$K = \frac{2{\cdot}3}{T} \cdot \log \frac{a}{a-x}$$

Temperature.	115°±1°C.		106°±1° C.		96°±1° C.	
a, g. per 100 c.c.	0·809		1·198		1·813	
T	$a-x$	K	$a-x$	K	$a-x$	K
2	0·490	0·25	0·920	[0·130]	1·657	[0·045]
3	0·368	0·26	—	—	1·644	0·033
4	0·291	0·26	0·838	0·089	1·600	0·031
5	0·248	0·24	—	—	1·542	0·032
6	0·202	0·24	0·628	[0·110]	—	—
7	0·164	0·23	—	—	1·469	0·030
8	0·120	0·23	0·608	0·085	—	—
9	—	—	0·570	0·083	1·381	0·030
10	—	—	0·504	0·086	—	—
11	—	—	—	—	1·299	0·030
12	—	—	0·417	0·088	—	—
13	0·032	0·25	—	—	—	—
Mean		0·245		0·086		0·031
Period of half-change ..	2·76 days		8·1 days		22·3 days	

It is apparent from the above results that even at comparatively high temperatures the rate of destruction of picric acid by nitrating acids is too slow to affect the yields obtained by the nitration of phenol.

Oriel College, Oxford.

ERRATUM.

MR. F. WALLS IN THE CHAIR.

THE HYDROLYTIC ALKALINITY OF PURE AND COMMERCIAL SOAPS.

BY F. C. BEEDLE AND T. R. BOLAM.

In two earlier communications from the Bristol laboratory,* which constitute the only quantitative measurements of hydrolysis in soap solutions, it was shown that the hydrolysis of soaps was unexpectedly slight.† The two independent methods involving E.M.F. measurements and catalysis prove that the hydrolytic alkalinity of soap solutions is negligible for most purposes since the concentration of hydroxyl ion is only about $N/1000$.

The object of the present paper was to obtain further data for pure salts of the fatty acids and to investigate soaps made with single typical oils as well as commercial soaps.

Experimental method.

Of the two available methods for the determination of hydroxyl ions in such solutions, the E.M.F. method suffers in the investigation of commercial soap from the serious drawback that the potential of the hydrogen electrode will probably be affected by the presence of unsaturated compounds. The method of the catalysis of nitrosotriacetone-amine‡ to give phorone was therefore adopted. The reaction is unimolecular, and the velocity is proportional to the concentration of hydroxyl ion. The volume method had been found to be accurate to within about 2 or 3% at the ordinary temperature.

The results are calculated according to the system proposed by McBain (Trans. Faraday Soc., 1917, 13, 1), which consists in always setting the rate-constant equal to unity and in choosing the unit of time accordingly.

The formula used here is consequently

$$T = 2{\cdot}303 \log. A/(A-x)$$

instead of the hitherto customary

$$k = 2{\cdot}303/t. \log. A/(A-x)$$

where k is the rate-constant. The disadvantages of the system hitherto employed, as compared with that proposed, are illustrated by the rate of reaction in the presence of 0·000656N OH′ at 90·0° C. The statement that "the rate-constant is 0·112" is meaningless until the further information is given that "time has been measured in minutes." Under the new system this becomes—"the time unit is 8·9 minutes"—a statement which is much more readily visualised, is self-contained, and does away with small decimals. It further means, in the case of unimolecular reactions such as the present, that the reaction requires 8·9 minutes to proceed to the extent of 63·2% or nearly two-thirds of completion.

The chief difficulty to be avoided in this method is the sorption of the amine by the soap in concentrated solution; so that dilute solutions containing not more than 1 g. in 100 c.c. of water had to be employed. It was soon found too that this influence persisted much more strongly at lower temperatures, and hence the temperature of 90° C. was adopted for the present experiments.

The values of the time units for definite concentrations of hydroxyl ion were measured by observing the rate in solutions of sodium hydroxide. These solutions were made up from sodium and boiled-out conductivity water. The reaction was carried out in a silver flask containing a small glass tube, which could be dropped into the solution in the flask when it was desired that the reaction should commence. In some cases this tube contained the soap solution, in others the solution of nitrosotriacetoneamine; 0·1300 g. of that substance was employed in each case.

The concentrations of the soap solutions are expressed in weight normality; that is, gram-equivalents of the soap per 1000 g. of water in the case of the pure soaps such as the oleate. The commercial soaps are expressed in "percentages"; that is, the number of grams of commercial soap contained in 100 c.c. of solution at room temperature. The values given in this column refer in the cases of sodium oleate and abietate to grams of anhydrous fatty acid in 100 c.c. of solution. The concentration of hydroxyl ion, on the other hand, is invariably expressed in volume normality at 90° C.

It is essential to flush out the vessels used with air free from carbon dioxide. Although with the soaps of the pure saturated fatty acids constant results were obtained for the time units and reaction constant throughout the whole course of any one reaction, nevertheless in most of the present cases which involve unsaturated fatty acids it was found that there is a tendency of the velocity of the reaction to fall below the value required for the unimolecular formula after the reaction has proceeded part way. This is possibly due to slight oxidation, and hence in all such cases the constant initial part of the reaction was taken as the basis of calculation of the hydrolysis-alkalinity given in the tables. A blank test showed that a solution of sodium oleate did not absorb a volume of air sufficient to affect the volume measurements.

In the first series of experiments carried out by one of us (T. R. B.), the value for the product C.T—that is, concentration of OH′ × value of time units at 90°—was found to be 0·00561, and this value was used for calculating with olive oil, coconut, toilet and cold process soap. In the remaining experiments (by F. C. B.) the value C.T = 0·00583 was used.

In all cases here recorded experiments were carried out at least in duplicate, and about ten readings were made in each experiment. The experimental results are summarised in Tables I. and II. The many interesting points arising are discussed under the separate headings below.

Pure sodium oleate.

Since all the data for pure soaps so far published refer to solutions prepared from pure saturated fatty acids, it is desirable to supplement them with data for an unsaturated fatty acid for comparison, particularly as this is an important constituent of some of the soaps studied here.

Oleic acid "Kahlbaum" was employed, and the solutions were prepared by Miss Laing, as in previous communications, using a quantity of alkali equivalent to the titration value in aqueous alcohol determined experimentally.

Examining the results of the tables, it is seen that the hydroxyl concentration (hydrolysis-alkali) passes through an absolute maximum in $N/20$ sodium oleate solution. The actual percentage hydrolysis is negligible at high concentration, but increases rapidly in very dilute solution.

Comparison with the previously communicated results of McBain, Bolam, and Martin shows that the hydrolysis-alkalinity of the oleate amounts to almost exactly as much as in the sodium and potassium palmitate.

In the case of all these soap solutions, it is probable that the maximum concentration of hydroxyl ions observed in about $N/20$ solution is quite real. Whilst in more dilute solution the percentage hydrolysis rapidly rises, this is counterbalanced by the diminishing concentration of the soap itself. With increasing concentration, on the other hand, the concentration of hydroxyl ion drops off owing to the gradual disappearance of the simple fatty ion and its replacement by colloidal ionic micelle, for it is the simple fatty ion only that is hydrolysed and the low values for the hydrolysis-alkalinity found with the catalytic method at high concentrations of soaps are only partially ascribable to the sorption of amine by soap. The attainment of the maximum hydroxyl ion concentration in the comparatively dilute ($N/20$) solution of sodium oleate is characteristic of the very colloidal nature of the oleates, since the oleate is more colloidal than the palmitate (maximum $N/10$), and very much more so than the abietate ($>N/10$).

Sodium abietate (rosinate).

For this constituent of washer and household soaps there were likewise no available data. The material employed was a specimen prepared by Miss K. M. Gibbons from best W.W. rosin. The rosin was boiled in anhydrous alcoholic solution of sodium ethoxide (free from carbon dioxide) for many hours in order to ensure complete saponification, and very carefully adjusted to give an exactly neutral solution when samples were tested with phenolphthalein in aqueous alcohol free from carbon dioxide. Thereupon the sodium salt was completely dried and analysed by Miss Laing.

The data in the tables show that the "abietic" acid is about as strong as palmitic and oleic acids, but that its salts being less colloidal, are more hydrolysed in stronger solutions. This agrees with other evidence which would place sodium rosinate amongst the lowest soaps.

Coconut oil and olive oil soaps.

Coconut oil is known to be a constituent of certain free-lathering soaps, some of which are said to have an action upon the skin, and olive oil soap is especially recommended for sensitive skins.

Thus Simmons* states: "The soap made from coconut oil has a rather irritating effect on sensitive skins, consequently the proportion of coconut oil in fats to be saponified for toilet soap should never exceed 25%," and again, "olive oil forms a very mild neutral soap especially adapted for sensitive skins . . . not a very good detergent."

It appeared of interest to inquire whether the irritant action of coconut oil soap was due to great hydrolytic-alkalinity or to some other cause, such as the presence of an active constituent or perhaps a specific action of the laurates themselves, which form the chief constituent of the oil.

Two special soaps were prepared from coconut oil and sulphur olive oil, respectively, through the kindness of Messrs. Christopher Thomas and Bros., Ltd., in lots of about ½ ton apiece. These were boiled in the ordinary way and "fitted" with the utmost care to produce a neutral settled soap. This was important, as the papers referred to have shown that any free alkali will partly remain present as such in the solution, and the hydrolytic-alkalinity would therefore be increased to that extent. Analysis of the olive oil soap showed only 0·008% of free alkali. These soaps were diluted with boiled-out conductivity water to form the solutions studied.

The tables show at a glance that, contrary to expectation, the coconut oil soap solution contained even less OH' than the olive oil soap. Free alkali could only account for 3·5% of the total hydrolytic alkalinity.

These data dispose of the presumption that soap solution with coconut oil as a constituent are more alkaline than those containing olive oil. Hence

* "Soap," W. H. Simmons, pp. 9, 10. (Pitman's "Common Commodities of Commerce" Series.)

irritation of the skin generally stated to be produced by a commercial free-lathering soap in dilute solution must be ascribed to something other than the actual alkalinity of the solution.

Evidence confirmatory of these views is to be found in the results for a soluble washer household soap as compared with a mere old-fashioned type of tallow-rosin household soap. The hydrolytic-alkalinity in both of these is identical (0·00077N and 0·00079N), and is nearly four times greater than that of a soap made from coconut oil alone.

Indeed, it would appear that the hydrolytic-alkalinity of soap solutions is essentially that produced by the most hydrolysable constituent, the others having but little effect.

Toilet soaps.

The tables include measurements carried out on a milling base for toilet soap containing 0·078% of free alkali by analysis. It will be noticed that the alkalinity of this soap is very slightly more than that of the pure olive oil soap.

McBain and Martin have shown that the degree of alkalinity of soap solutions rises rapidly as the homologous series of fatty acids is ascended, and, of course, as indicated above, the most highly hydrolysed constituent of the solution will be the chief controlling factor in the determination of the hydroxyl ion. This would ascribe the high degree of hydrolysis to the important amounts of higher saturated fatty acid present, although the alkalinity falls appreciably short of that of a pure sodium palmitate solution, being in this case about 75% of the value obtained for the latter. This bears out the results obtained by McBain and Martin with toilet soaps in much more concentrated solution. Household soaps, on the other hand, they found to be less alkaline than the toilet soaps, but the values obtained in this case were open to serious doubt on account of the effect of unsaturated constituents on the hydrogen electrode.

In dilute solutions the household soaps are not very much more alkaline than the best toilet soap, and, if anything, rather less so than the coal tar soap, which is sometimes recommended by the medical profession for sensitive skins. The most alkaline soap examined is an imported shaving soap, probably because it contains so much stearate.

Cold process toilet soap.

Simmons also states (*loc. cit.*, page 37) that "since fats and oils can never be completely saponified without an excess of alkali, and it is obviously impossible to add such an excess to a cold process soap without getting a strongly alkaline soap . . . cold process soaps always contain small amounts of free acid and uncombined alkali . . . and uncombined alkali has, of course, an irritating action on the skin."

Consideration of the low temperature-coefficient of heterogeneous reactions would make this statement appear very doubtful, and the evidence of the measurements in the tables show that saponification is complete. The specimens used were samples of commercial soap of English manufacture, and the measurements were made as soon as possible after making up the solutions. The alkalinity of the solutions is so like that of the other soaps that it is probably all due to hydrolysis.

Sodium carbonate.

Simmons (*loc. cit.*, p. 25) states that "sodium carbonate has an irritating effect on sensitive skins, and consequently must only be present to a very small extent in a toilet soap, usually not exceeding 0·15%. The experiment gave a concentration of hydroxyl ion in 0·15% sodium carbonate solution at 25°, amounting to 0·0010 N. This is very interesting, for although alkalinity rises rapidly with rise of temperature, very hot water cannot be employed in washing. Thus a maximum alkalinity recognised as permissible is about 0·001—0·002N OH′, which is exactly equal to the maximum alkalinity hitherto recorded for a commercial soap, namely in a well-known imported shaving soap measured at 90° in rather high concentration by McBain and Martin (*loc. cit.*; see also Tables I. and II. for the dilute solution), and which is at least twice as much as obtains for any of the concentrations of soap solutions included in Tables I. and II.

Summary.

1. The free alkali contained in any well-made soap, intended to be neutral, accounts for only a fraction of the alkalinity (OH′) which is observed in dilute solutions of soap and which is due to hydrolysis.

2. The hydrolysis-alkalinity of dilute soap solutions rarely amounts to $N/1000$; that of concentrated solutions not more than $N/500$. The latter alkalinity is that which corresponds to about 0·15% of sodium carbonate, larger quantities of which should not be found in toilet soaps.

3. Sodium oleate and the sodium salt of rosin are about as much hydrolysed as the palmitate, but in stronger solutions the oleate is less and the rosinate more hydrolysed in correspondence with their respective degrees of colloidal properties.

4. Soap prepared from pure coconut oil has an exceptionally low hydrolytic-alkalinity. Neutral soap from pure olive oil exhibits a hydrolytic-alkalinity similar to good toilet soap and slightly exceeded by household soaps and some other toilet soaps.

5. The hydrolytic-alkalinity of a soap solution appears to be chiefly conditioned by the most hydrolysable constituent present. Thus shaving soap exhibits a high degree of hydrolytic-alkalinity. Similarly, the hydrolytic alkalinity arising from coconut oil soaps does not account for any irritating action on the skin. Such action must be ascribed to some other constituent present, such as, possibly, a specific action of the laurates contained in it. Soaps consisting largely of the more readily sorbed soaps of the higher fatty acids should not exhibit irritating action upon sensitive skin, as in these mixtures sorption of such constituents as the laurates by the skin will be largely obviated.

6. A free-lathering soluble washer household soap exhibits about the same hydrolytic alkalinity as a tallow rosin (0·0008N OH′).

7. A well-made cold-process soap does not exhibit hydrolytic-alkalinity appreciably greater than could be expected from any toilet soap made from the same materials. In other words, the OH′ concentration is too small to have an effect even upon sensitive skin.

In conclusion, we desire to thank Prof. McBain for the interest he has shown in our work, which was undertaken at his suggestion, and the Colston Society of the University of Bristol and the Chemical Society of London for grants in aid of the investigation.

London Section.

Meeting held at Burlington House, on January 3, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE ANALYSIS OF LIQUID AND GASEOUS MIXTURES OF ETHER, ALCOHOL, AND WATER.

BY IRVINE MASSON AND T. LAWSON McEWAN.

Despite the widespread applications of ether-alcohol as a solvent on the large scale, especially in the nitrocellulose industries, the published methods of analysis of these mixtures are either tedious or

unreliable, and in any case approximate only; and for the analysis of mixtures of the vapours diluted with air, which should serve to control processes for the recovery of evaporated solvent, satisfactory methods appear to have been entirely lacking (*cf.* Mallinckrodt and Alt, J. Ind. Eng. Chem., 1916, 8, 807; Wolff, Chem.-Zeit., 1910, 34, 1193; Kochmann and Strecker, Biochem. Zeits., 1912, 43, 410). The methods now described were therefore devised and tested, and were adopted at Gretna and other cordite factories during the war.

Fleischer and Frank (Chem.-Zeit., 1907, 31, 665) described an approximate method in which the aqueous ether-alcohol sample was shaken with water and paraffin ("Benzin"), the increase in volume of the oil being taken as the volume of ether present. From this and from the density of the sample the apparent density of the alcohol-water portion was algebraically calculated, and the strength of this found from ordinary alcohol tables. It was thus assumed that all the ether was extracted by the oil, and, further, that no change in volume takes place on mixing ether with aqueous alcohol. As the sequel shows, neither assumption is correct, and the results deviate from the truth by about 10% for the ether and by much more for the alcohol.

By using extraction with paraffin and water, however, if due allowance be made for the partition of ether and alcohol between the two layers, the ether content of a sample can be found within less than 1% of the truth; and if this result and the density of the sample are compared with actual experimental data for the densities of synthetic ternary mixtures, the alcohol content may be found with an accuracy of 1%.

In the case of vapours similar principles apply to the ether estimation, the vapours being first absorbed in sulphuric acid.

A.—*Liquid mixtures.*

Paraffin, water, ether, and alcohol together form two layers, of which the upper contains all the paraffin, most of the ether, and a part of the alcohol. If sufficient water be present to reduce the concentration of alcohol in the aqueous layer below about 25%, little alcohol can pass into the upper layer with the ether; similarly, excess of paraffin improves the extraction of ether into the upper layer. These conditions are met if 1 vol. of the sample is shaken with 2 vols. of paraffin and 2 of water. In these circumstances the volume of the paraffin increases by an amount which may be between 80% and 105% of the volume of ether actually present, according to the kind of oil used and, to a slight extent, on the ether content of the sample tested.

The light paraffins give the highest apparent efficiency of extraction; heavier varieties, such as centrifugal oils and paraffin "B.P." give emulsions or are too viscous. Two qualities are here specified. For ordinary purposes by much the best is petroleum ether, of sp. gr. 0·68 at 20°/4°, b.p. 40°—75° C. For special cases, to be referred to later, a mobile paraffin of sp. gr. 0·75 at 20°/4°, b.p. 120°—140° C., is used; lamp oil, even after purification, is an unsatisfactory substitute. A convenient source of the oil is the xylene fraction of Borneo oil, as obtained from the Asiatic Petroleum Company; this oil is treated at 100° with oleum to remove aromatic and unsaturated hydrocarbons, and is shaken successively with alkali, water, anhydrous calcium chloride, and mercury, being finally filtered. Other sources are doubtless available.

Emulsification is avoided by the use of water containing a little acid (2% H_2SO_4) for the extraction.

Finally, owing to the high coefficients of expansion of ether and of petroleum ether, due care must be taken in analysis to counteract the rise of temperature which occurs on mixing alcohol with water. The actual distribution of the components seems to be little affected by this temperature change, so that where weighing is adopted no such precaution is necessary.

(*a*) *Estimation of ether.*

(i.) *Large samples.*—A separating-funnel containing 200 c.c.$\pm$1 of petroleum ether as already specified is weighed to 0·1 gram. 100 c.c.$\pm$0·5 of the sample is added and the weight again taken. 200 c.c.$\pm$1 of water containing 2% H_2SO_4 is added without weighing, and the corked vessel is vigorously shaken, after which it is allowed to stand for a few minutes with occasional rotation. The aqueous layer is now run off so that a few c.c. remains, and the corked vessel allowed to stand for ten minutes, adherent drops of moisture being released by intermittent swirling. The aqueous layer is now finally run off and the vessel and contents weighed. The total time required for the analysis is 20 minutes.

The gain in weight of the oil is about 90% of the true weight of ether present; the true value is found from a curve which should be drawn from the determinations with synthetic mixtures recorded in Table I. The accuracy of the result is within 1%, excepting where much water is present in the sample, when the value read from the curve is low by 1% (see Table I.).

TABLE I.

Ether extraction by petroleum ether.—Weight method.

(Ether-alcohol-water, 100 c.c.; p.e., 200 c.c.; 2% H_2SO_4, 200 c.c.)

Mixtures with 94% spirit.			Mixtures with 75% spirit.

53·3	49·3	0·93			
58·1	53·1	0·92			
71·2	65·1	0·92	17·8	15·6	0·88
			33·9	30·7	0·92

(ii.) *Small samples.*—Where only 20—30 c.c. of liquid is available the following method is accurate. A burette of 100 c.c., graduated in tenths, has bound to it a thermometer, with its bulb kept closely in contact with the burette at about the 30 c.c. mark by means of rubber rings. A jacket of cotton wool is wrapped around the bulb and burette at this point. Mercury is put in up to the lowest mark; 40 c.c.$\pm$0·1 of water containing 2% H_2SO_4 is added, and 40 c.c.$\pm$0·1 of petroleum ether. The burette is corked, and after 5 minutes' settling the exact volume of the upper layer is read and the temperature noted. From another burette 20 c.c.$\pm$0·1 of the ether-alcohol-water sample is measured into the analytical burette. This is then tightly corked and is inverted 15 times, with vigorous shaking, after which it is allowed to stand upright for at least 10 minutes, with occasional twirling between the hands, the temperature being finally reduced to the initial value. The volume of the upper layer is now read and the increase noted. A difference in temperature of 1° C. between the readings affects the result by 0·3%. The increase in volume is about 90% of the true volume of ether. The experimental data, from which the conversion curve is to be drawn, are given in Table II.

(*b*) *Complete analysis.*—This entails a determination of ether content as described, together with a measurement of sp. gr. at 20° C. The densities of

forty synthetic mixtures were determined, and are given for reference in Table III; from these the figures of Table IV were obtained by graphic methods. The curves of the diagram corresponding with Table IV (which does not lend itself to accurate reproduction on a small scale) give by inspection, from the ascertained ether content and sp. gr., the required alcohol content of the sample; the percentage of water follows by difference.

20·00	18·82	0·94			

The accuracy of the method is within 1% for ether and alcohol.

B. Vapour mixtures.—The vapours can be completely absorbed in strong sulphuric acid, and nearly all the ether can be extracted with paraffin if the acid be then suitably diluted. If alcohol and water are to be jointly determined, the gain in weight of the acid is measured before extracting the ether; the results give the alcohol+water by difference. Where, however, it is desired to estimate each constituent, the air-stream bearing the vapours is drawn first through ignited alumina, which extracts the moisture and leaves only the alcohol and ether to be absorbed by the acid. Thus two pairs of weighings and one paraffin-extraction, made with a single sample of the vapour-laden air, give a complete analysis.

The alumina is prepared by precipitation with ammonia from aluminium nitrate; after thorough washing it is ignited at a dull red heat. The white crumbly product is very hygroscopic, and is the only material found to absorb moisture sufficiently rapidly without retaining notable quantities of alcohol and ether.

Whatever type of acid-bubbler is used should be chosen with a view to ease in pouring out as well as to efficiency and lightness; it need not have a capacity greater than about 30 c.c. One bubbler next to the alumina tube is filled with 10 c.c. of pure sulphuric acid (sp. gr. 1·84), and a second with 5 c.c. The two are weighed (unless ether alone is to be determined, when neither weighings nor alumina-tubes are required) and are connected in series with the alumina-tube on one side, and with a graduated aspirator on the other through a guard-

* In drawing curves of these data density should be plotted against ether-content, each of the above columns forming one of the curves of the diagram,

tube containing sulphuric acid. The air-sample should contain less than 5 g. of ether, and the rate of aspiration may be as rapid as the efficiency of the absorbers will allow. It is advisable to stand the acid-bubblers in cold water. At the end of the absorption any alcohol which is present in the alumina is removed by means of a stream of dried air; the absorption tubes are then weighed (for water and for alcohol+ether), and the ether-determination is made.

For this purpose a burette of the Mohr type is used, having a stem of 50 c.c. graduated in tenths and terminating below in a bulb of capacity not less than 80 c.c. A thermometer with cotton wool wrapping is attached, as described above. Before the analysis, mercury is put into the burette up to the lowest mark.

The principal bubbler is now emptied into the burette, and is washed in with the contents of the second. Enough sulphuric acid (sp. gr. 1·84) is added to bring the volume of the acid layer to 20 c.c.±0·1. Mercury is then run out to make room for the addition of 40 c.c.±0·2 of the mobile paraffin already specified, the volume of which is exactly read *in situ* after draining. More mercury is run out, and 50 c.c.±0·2 of water is carefully added, the burette being tilted; a cork is at once inserted and is held firmly while the acid and water are gently but thoroughly mixed, the burette being cooled by means of water. The burette is now inverted 12 to 15 times, and is read in the same manner as described above. The gain in volume of the oil is from 70 to 84% of the volume of ether actually absorbed; the conversion is given in Table V, from which a curve should be drawn. Excess of alcohol vapour does not affect the ether-determination.

TABLE V.

THE RECOVERY OF SOLVENT-VAPOURS FROM AIR. THE USE OF CRESOL AND OF SULPHURIC ACID FOR ETHER AND ALCOHOL.

BY IRVINE MASSON AND T. LAWSON McEWAN.

The recovery of solvent-vapour from air into which it has been evaporated has for many years been in operation in the case of cordite factories using acetone, the absorbing agent used for this solvent being an aqueous solution of sodium bisulphite (the Robertson-Rintoul process, E.P. 25,994 of 1901). With the development of cordite R.D.B., there arose the need for recovering ether-alcohol, another absorbent being required; and the economic value of the recoverable ether, alcohol, benzene, etc., used in other nitrocellulose and in rubber industries is great. Several methods suggested for such purpose, which have been tried on the full scale, have failed owing to fundamental unsoundness which preliminary physico-chemical work in the laboratory would have discovered.

The present paper gives a short account of two laboratory investigations dealing with the use of cresol* and of sulphuric acid respectively, for the recovery of ether-alcohol vapours highly diluted with air; and they include a contribution to the calculation of scrubbing-efficiencies in general. The investigations relate, first, to the efficiency with which the scrubbing liquid can absorb the vapours, and, secondly, to the conditions for separating the absorbed material from the liquid.

CRESOL.

A.—Absorption.

The efficiency of absorption of a vapour by a non-volatile liquid depends in the first instance on the vapour pressures of liquid mixtures of the two. Measurements were therefore made of the vapour pressures at various temperatures of solutions in different concentrations of ether and of alcohol in cresol, pure and crude. Two experimental methods were used: in one a jacketed nitrometer (with mercury-sealed tap) and its reservoir served as a barometer into which the liquid mixture could be introduced; in the other, known volumes of air were drawn through the liquid in appropriate saturators, the quantity and composition of the vapour so evaporated being determined. In both methods there are inherent possibilities of error, but these can be avoided; and the results obtained were in sufficiently close agreement with each other and with the standard data by which they were tested, for all practical purposes. The effects of moisture (present in the air to be scrubbed) were also tested; the ranges of temperatures and of vapour-concentrations were restricted to those to be expected in practice.

The latent heats of solution of liquid ether and of alcohol in cresol at ordinary temperature were also measured, in order to calculate thermal effects in the scrubbers, and were found to be respectively 60 Cals. and <2 Cals. per kg. of liquid dissolving in 4 kg. of cresol.

Some of the vapour pressure data are given in Table I., corrected for the slight partial pressures of cresol, and expressed in grams of vapour per cubic metre. It will be found that, for the concentrations concerned, the curves are practically rectilinear and Henry's law holds. At higher concentrations (not recorded here) the curves first steepen and finally flatten again, as is usual with such mixtures.

It was proved that when alcohol and ether are present together in cresol, each has little or no

* The use of cresol was the subject of a patent by Brégeat: E.P. 128,640.

significant effect on the partial pressures of the other; nor, except at the higher temperatures, does the presence of dissolved water materially affect the partial pressure of ether in cresol.

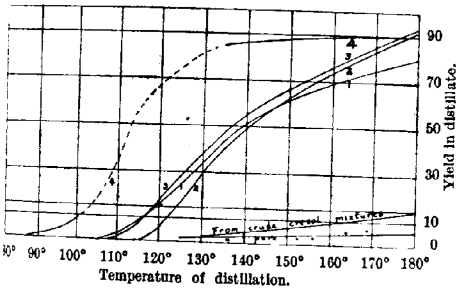
B.—Regeneration.

The recovery of the absorbed vapours was obviously to be accomplished by distillation; hence measurements were made of the yields got at different temperatures by distilling ½-kg. samples of 20% solutions of solvent in cresol—a strength which the vapour pressure measurements had indicated would be the maximum to be dealt with in practice. A method for analysing the distillates (described in another paper) was worked out and used.



Temperature of distillation.

FIG. 1.

The tenacity with which cresol retains ether and alcohol, even at high temperatures, as shown by curves 1—3 of Fig. 1, pointed to the need for steam-distillation; experiments with this, recorded in curve 4, confirm the necessity and define the temperatures to be used. Finally, since cresol is itself slightly volatile, the distillates were analysed for this component; the results are shown in the lowest curves of Fig. 1.

C.—Application of data.

The plant initially available on the full scale consisted essentially of scrubbing towers built up of tray-segments, the vapour-laden air bubbling up through the trays in series in counter-current to the liquor, which thence passed to stills; the absorbent, now freed from solvent, was cooled and returned to the beginning of the cycle.

(a) *Absorption.*—The efficiency of absorption is throughout expressed as the percentage of the entering weight of vapour which is removed from the air by the scrubbing-liquid. Provided that equilibrium is established at each contact of vapour-laden air with absorbent, the efficiency would be affected only by (1) the temperature, (2) the flow ratio, *i.e.*, weight of absorbent used per cb. m. of air, (3) the concentration of solvent which may be already present in the absorbent, and (4) the number of "effects." Under equilibrium conditions, in a case like the present one, to which Henry's law applies, the concentration of vapour in the entering air has in itself no influence on the efficiency as defined, except through the thermal effects referred to below.

In practice, true equilibrium is not achieved in each "effect"; but no data as yet available for a tower-design suffice for the quantitative application of a theory of counter-current scrubbing (*cf.* Donnan and Masson, J., 1920, 236—240 T). If, however, we calculate the relationships between flow-ratio, number of effects, and efficiency, on the assumption that equilibrium is attained at each effect, we can at least establish the minimum requirements which must be met to achieve specified efficiencies; this will now be exemplified.

Thermal effects.—The temperature of the air-stream varies with different local conditions; that of the towers varies from top to bottom owing to the heats of absorption. The latent heat of condensation of alcohol is 250 Cals. per kg.; that of ether is 90 Cals. per kg., to which must be added about 60 Cals. for the heat of solution in cresol; and the specific heat of cresol is about 0·55. Thus if the air reaching the scrubbers contain, for example, 40 g. of alcohol and 20 g. of ether per cb. m. the heat liberated by the absorption of this could heat 1 kg. of cresol through about 23° C., or 1 kg. of cresol + 1 cb. m. of air through about 15°. This figure would be increased, and the efficiency in consequence lowered, if the incoming air were richer in vapour or if the flow-rate of cresol were to be reduced. From the data about to be discussed, it appears that a rise of mean temperature of 10° would reduce the efficiency by roughly 5—10%; but the question is one of temperature-gradient and heat interchange, and is not at present amenable to more exact calculation. We may nevertheless reckon isothermally with a mean *effective* temperature, bearing in mind the fact that the efficiencies so deduced will approximate most nearly to the truth when the vapours are dilute and the liquor-feed is high; and by adopting here an effective temperature of 30°, we provide a margin and in a simple way obtain (as will be seen) results well borne out in practice and therefore useful as a forecast of the working conditions to be adopted.

Efficiency of absorption.—We may define Henry's coefficient (k) as the equilibrium-ratio between the weight of substance dissolved per kg. of cresol and the weight remaining as vapour per cb. m. of air. For ether at 30°, $k = 1·06$; hence if 1 cb. m. of ether-laden air be brought to equilibrium with 1 kg. of fresh cresol, $1·06 \div 2·06 = 51·5\%$ is the efficiency of absorption. For alcohol at 30°, k is 4·32, and the efficiency is $4·32 \div 5·32 = 81\%$. The absorption of ether is thus the dominant problem.

In general, if q kg. of absorbent be brought into equilibrium with 1 cb. m. of air, then whether the absorbable constituent were initially all in the air, all in the absorbent, or divided between them, the final result would be that, of the *total* weight of it present, a fraction $qk/(qk+1)$ must remain in the liquid. (Where Henry's law is not applicable and k is not a constant, the values of this fraction for the concentrations dealt with are found from the experimental curves.)

The values of $qk/(qk+1)$ for ether at 30° and for flows of 0·4, 0·6, 0·8, 1, and 2 kg. of cresol per cb. m. of air are 30, 39, 46, 51·5, 68% respectively; with a single "effect," these numbers are the efficiencies of absorption.

Now consider a two-effect counter-current scrubber, with a specified feed of 1 kg. of cresol per

cb. m. of air, containing, say, 100 g. of ether vapour per cb. m. The first cubic metre admitted meets the layer A in the bottom effect, and 51·5% is absorbed as explained above; 48·5 g. of vapour passes on to layer B in the upper effect, which absorbs 0·515×48·5=25 g.; the remaining 23·5 g. of vapour is lost. The layer A now flows out of the tower and a second cubic metre of air with 100 g. of ether meets first the layer B, now occupying the lower effect, and already charged with 25 g.; hence of the *total* 125 g. 51·5%, or 64·5 g., is absorbed, the remaining 60·5 g. passing up to the fresh top layer, C. Proceeding in this way for each successive admission of air and its accompanying flow of liquid, we obtain the results shown in Table II.

Thus after 4 cb. m. of air has passed, a steady state is reached, the recovery being henceforth 68·5%.

We may similarly calculate the efficiencies for other flow-rates, using the appropriate values for $qk/(qk+1)$, and for any specified number of effects. (General algebraic formulæ, which might replace this arithmetical method, grow too cumbersome with many effects). A separate calculation is made for each type of system and for each different flow-rate. The results of these calculations for ether at 30° C. are shown in Fig. 2, which includes also a curve for 20° and two curves for alcohol at 30°. From this can be judged the maximum efficiency of counter-current absorption which can be reached with cresol, working either with a single effect or with multiple effects up to six, and feeds of cresol up to 1 kg. per cb. m. of air-stream.

It is clear that increasing the number of effects much beyond six is necessary only to make up for the non-attainment of equilibrium in each effect, which is in turn due to the finite velocity of dissolution of a gas, to excessive thermal effects caused by "waves" of vapour, and to imperfections in the design of the scrubber. A feed of 1 kg. of cresol per cb. m. of air should give a recovery of over 90 with six to eight effects at an effective temperature of 30°. Experience on the large scale has justified this conclusion.

FIG. 2.

(b) *Regeneration.*—Fig. 1 is self-explanatory. It is evident that steam-distillation is called for, and that unless local rectification is provided, 3—5% of the primary distillate will be cresol, which will have to be returned to the system. One kg. of cresol containing 40 g. of alcohol and 20 g. of ether would require, for heating it from 30° to 130° with separation and distillation of the vapours, roughly 70 Cals. (specific heats of ether and of alcohol vapours=0·44 approx.); while the remaining cresol will require to be cooled to, say, 15° before re-use, therein parting with about 65 Cals.

It is not proposed to deal with certain other factors affecting the use of cresol, such as the presence of naphthalene and of pyridine homologues in the crude material; the slight loss of cresol in the air issuing from the scrubbers, corresponding with its measurable vapour-pressure at low temperatures; its increase in viscosity after long use; and its attack on metals other than iron and steel. These were well investigated by the Research Laboratories of H.M. Factory, Gretna, where the installation of the cresol process on a large scale led to most satisfactory results.

SULPHURIC ACID.

The general procedure in this case was the same as with cresol, with additional work called for by two variants not paralleled in the case of cresol, namely, the strength of the sulphuric acid and the chemical action of the more concentrated acids upon alcohol.

A.—Absorption.

The vapour-pressure results, recorded in Table III., showed that while Henry's law is approximately valid for each strength of acid within the range of the experiments, the solubility of ether vapour in particular varies from small to great according to the concentration of the acid dealt with. The solubility-coefficients (k) for ether range from 0·02 with 50% sulphuric acid at 30° C., to 4·2 for 82% acid at 20°.

We may thus consider the general relations between solubility-coefficients, k, as determined in the laboratory, and the efficiencies of absorption obtainable in scrubbers.

To decide the merits of an absorbent for a given vapour, we must first ascertain from the vapour pressures whether the value of k is such as will

10·0	0·50	0·75	0·88	0·91	0·94	0·95	0·97	0·98	0·99

bring $qk/(qk+1)$ above the critical value when the flow-rate (q) is kept within reasonable limits. This can conveniently be ascertained from Table IV., which applies to any vapour and absorbent of the general type dealt with.

Thus, once the solubility-coefficient of the vapour in the proposed liquid has been determined, reference to Table IV. enables us to see what flow of the liquid is needed to give values of $qk/(qk+1)$ sufficient to correspond with high efficiencies, as set forth in Table V., where the number of effects which will be required is stated. Each figure in this table is the result of a separate calculation such as that exemplified on p. 34 T.

It is seen that no really useful absorption can be expected when $qk/(qk+1)$ is less than about 0·5, as shown to the left of the zigzag line in Table IV.

Solubility of vapours in sulphuric acid.

Fig. 3.

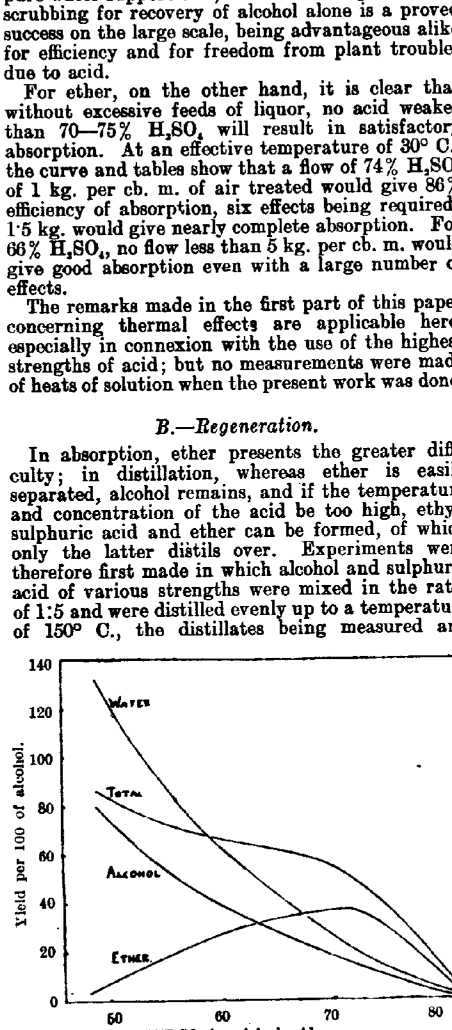
Turning now to the particular case before us, the values of k, the solubility-coefficients, are given for ether and for alcohol in Fig. 3. Reference from this to Tables IV. and V. at once shows that alcohol is very easily absorbed even in acid as weak as 50% H_2SO_4; the coefficients are so high that difficulty would be anticipated—and is in fact met with, as will be seen—in expelling the dissolved alcohol from acid by distillation. The trend of the curves indicates that a sufficiently high value for k (alcohol) would be given by 0% H_2SO_4; direct determinations of the partial pressure of alcohol in pure water support this, and the use of pure water-scrubbing for recovery of alcohol alone is a proved success on the large scale, being advantageous alike for efficiency and for freedom from plant troubles due to acid.

For ether, on the other hand, it is clear that without excessive feeds of liquor, no acid weaker than 70—75% H_2SO_4 will result in satisfactory absorption. At an effective temperature of 30° C., the curve and tables show that a flow of 74% H_2SO_4 of 1 kg. per cb. m. of air treated would give 86% efficiency of absorption, six effects being required; 1·5 kg. would give nearly complete absorption. For 66% H_2SO_4, no flow less than 5 kg. per cb. m. would give good absorption even with a large number of effects.

The remarks made in the first part of this paper concerning thermal effects are applicable here, especially in connexion with the use of the highest strengths of acid; but no measurements were made of heats of solution when the present work was done.

B.—*Regeneration.*

In absorption, ether presents the greater difficulty; in distillation, whereas ether is easily separated, alcohol remains, and if the temperature and concentration of the acid be too high, ethyl-sulphuric acid and ether can be formed, of which only the latter distils over. Experiments were therefore first made in which alcohol and sulphuric acid of various strengths were mixed in the ratio of 1:5 and were distilled evenly up to a temperature of 150° C., the distillates being measured and

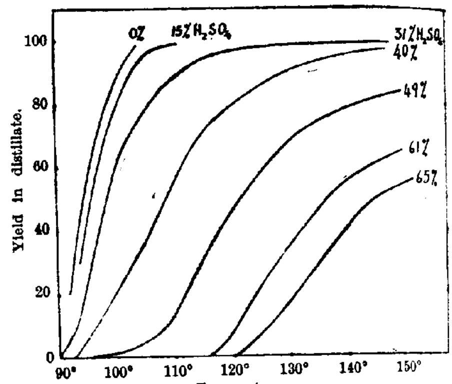


Yields on distillation to 150° C. of 100 grams alcohol + 500 grams sulphuric acid.
(Ether is expressed in terms of alcohol).

FIG. 4.

analysed by the method described on p. 29 T. Fig. 4 shows the results obtained with acids which contained over 50% H_2SO_4 before being mixed with alcohol. The various curves show the total recovery (up to 150°) per 100 g. of alcohol originally present, the separate amounts recovered as alcohol and as ether respectively, and the associated water which distils over. The ether-yield is expressed in terms of the weight of alcohol from which it was formed during the distillation.

Considering the total recovery, it is seen that with 82% H_2SO_4 practically no liquid distils over up to 150° (SO_2 being evolved in considerable quantity); with 70% acid a 55% recovery is reached, of which about three-fifths appears as ether and two-fifths as alcohol; 60% acid gives 66% recovery, the proportions of alcohol and ether recovered being reversed; 50% acid gives 83% recovery, only one-twelfth now being ether. It was found that increasing the rate of heating made very little difference in the yield or composition of the distillates, nor did the presence of added ether materially aid the recovery. It is evident that to achieve proper recovery in one distillation the acid must be diluted to be at most 50% H_2SO_4 (not counting the alcohol present).



Yields on distillation of 100 grams alcohol + 500 grams sulphuric acid of specific strengths (any ether formed is included in terms of alcohol).

FIG. 5.

A second series of distillations was therefore made with acids weaker than 50% H_2SO_4, the results of which, shown in Fig. 5, enable the yield on distillation to any desired temperature with specified strengths of acid, to be gauged.

The distillates obtained naturally become more aqueous the higher the yield extracted. At yields of 80%, the spirit obtained from 51% H_2SO_4 is 28% alcohol; from 49% H_2SO_4 it is 44%; and from 31% H_2SO_4, 55%.

Finally, there is the question of the strength of the acid after it has been subjected to distillation. With acids stronger than approximately 65% H_2SO_4 heated to 150° with alcohol, the chemical formation of ether sets free more water than is removed by distillation, so that the final acid is of about 65% strength. With weaker acids, ether-formation takes place either to a less extent or not at all, and distillation results in concentration. The net result is to give acid of 60—65% H_2SO_4 at temperatures of 140°—150°, and of 50—55% at 130°.

C.—*Conclusions as to the use of sulphuric acid.*

(1) On account of the difficulty of absorbing ether, 74% H_2SO_4 will require to be supplied to the scrubbers, with a flow-rate not less than 1¼ kg. per cb. m. of air treated, and with at least six effects in the scrubber. Alcohol will be very thoroughly absorbed. With more concentrated acid the feed can be less, according to the tables; but it is probable that thermal effects would then outweigh the advantage gained.

(2) In the absence of alcohol, distillation of the effluent liquor at low-pressure steam temperatures will readily yield up practically all the ether; but

when alcohol is present, it is essential that the effluent be diluted to be below 50% H_2SO_4 and preferably to 40% H_2SO_4 (not counting the absorbed solvent present) before it is distilled. The distillation must then be carried up to 150° for acid diluted to 50%, or to 130° with 40%, in order to regain nine-tenths of the absorbed alcohol.

(3) The acid resulting from the distillation at 150° will be about 60% H_2SO_4, or 50% H_2SO_4 from that at 130°, besides containing some remaining unexpelled alcohol in the form of ethylsulphuric acid. In a cyclic recovery process, this would require to be separately concentrated up to 74% and cooled, before being returned to the top of the scrubbers.

(4) Thus it will be seen that, while sulphuric acid of about 75% strength would be of the same degree of utility as cresol if ether were the only substance to be recovered, where both ether and alcohol together are concerned, it cannot compete with cresol on account of the heavy costs attaching to the re-concentration which is required. Where alcohol alone is in question, the simplest efficient absorbent is water.

(5) In the course of the paper two tables, based on vapour pressures, are given which specify, for any simple scrubbing liquid and any gas, the minimum rates of flow and numbers of "effects" required to give stated efficiencies of absorption.

The authors' acknowledgments are due to the Director of Artillery for permitting publication; to Sir R. Robertson and Mr. A. E. Leighton for their interest in the work; and to Mr. H. Swann and Mr. H. Whittaker for their assistance in the experiments.

Discussion.

Sir Frederic Nathan said that the papers gave the genesis of the work which had led to a very important step in connexion with the production of propulsive explosives. The recovery of acetone from cordite was well known, but the introduction of an explosive with ether and alcohol as the solvent involved another recovery problem. For the reasons given by the authors, and also more especially owing to the fact that it was impossible to use sulphuric acid in existing recovery plants, it had never become practicable to employ it. Fortunately the value of cresol as an absorbent of ether and alcohol had been realised, and as the result of the experiments described the recovery of very large quantities of alcohol and ether had been made possible, and in that way the cost of our explosives had been reduced.

Sir Robert Robertson said that the earlier experiments on the absorption of ether and alcohol by sulphuric acid had shown clearly that this process was inadvisable, at least under the conditions which existed in this country. The necessary dilution of the sulphuric acid used for absorption, before it would part with its ether and alcohol, had constituted an objection, as it involved the reconcentration by heating of large quantities of sulphuric acid. This was to be avoided in the neighbourhood of propellant manufacture, on account of the possibility of fumes from the condensation apparatus getting into the danger area, which in this respect should be kept scrupulously clean. That danger, however, did not arise with the use of cresol. It was from the results of the authors' investigations that they had deduced the conditions and expressions which defined the maximum efficiency of a solvent, not only for the solvents mentioned, but also generally. For cresol the results actually obtained in practice agreed well with those predicted by this work, and in another case known to the speaker an application of the same principles to the absorption of alcohol by water gave a result which was in good agreement as regards percentage of possible recovery with actual results obtained in both experimental and large-scale practice. The principles worked out by the authors should therefore be found useful in connexion with the absorption of vapour by solvents, the main assumption being that equilibrium between absorbent and vapour is achieved. He understood that Dr. Masson was pursuing his investigations on this subject; the absence of the data in this connexion had in the past resulted in many plants being built much larger than was necessary.

Mr. F. Sproxton said the authors had referred to the difficulties which occurred when applying his results to large-scale plant, but he had not referred to some almost equally great difficulties which occurred, particularly in the celluloid industry, before this stage was reached, namely, in obtaining a constant concentration of the solvent vapour in the air which had to be dealt with. He thought this was a more difficult problem in the case of celluloid than with cordite, for the reason that there was a larger range of thicknesses in celluloid manufacture. The thinnest material was 0·005 in., and the thickest standard material about ¾ in. thick. With the thinnest sheets all the solvent which might be got out had gone in a few hours, and so far it had been almost impossible to find a practicable way of recovering any of this solvent. After the material was booked and weighed there was very little left. He did not think the difficulties were so great in the case of the dope industries, because there they were dealing with large quantities of solvent in comparison with the solid residue. In the case of celluloid there was only about 10% of the raw weight to recover. Although in the celluloid industry there might be a very large number of stoves it was not possible to have one stove for every thickness, and consequently there would be a stove with half the material ready to come out and the other half still giving off vapour. Many of the patentees of methods of solvent recovery had not realised the difficulties antecedent to the actual recovery process.

Dr. W. R. Ormandy said the authors had given in a very lucid manner the theory underlying the important practical work which M. Brégeat had done since 1916. Since then a large number of plants had been put up to work with cresol, and if the facts and figures could be obtained from M. Brégeat they would add to the value of the present paper. The most remarkable thing to him in connexion with the work was the apparent capability of cresol to absorb most of the vapours which were used industrially. Was there any connexion between the latent heat of solution and this property of the cresols to absorb a large proportion of the vapours which were present in the air? Obviously, the best liquid for the purpose was the one which absorbed the largest proportion in the liquid and left the smallest proportion in the air. It was a very interesting fact that many of the hydroxybenzene compounds, such as the thymols, which were very insoluble in water, were remarkably soluble in water which contained phenols and cresols, and this rather bore on the curious property of the cresols to dissolve so many of the vapours used industrially.

Mr. William Macnab said he believed that the greatest dilution of air with ether and alcohol that could be successfully treated was 5 grms. per cubic metre. In France M. Brégeat's method had been used on a much larger scale than at Gretna, but in both cases it had resulted in a great increase in the recovery. At Gretna it had been a very great success, and had saved a large amount of alcohol. He hoped before long some information would be published on the actual working of the plant in regard to which much of Dr. Masson's work referred.

Dr. Masson, in reply, said that at Woolwich they had measured the vapour pressures of a large number of volatile solvents dissolved in cresol, and in every case the results were such as led him to suppose that even volatile oils such as some of the hydrocarbons could fairly well be dealt with by cresol. That, he believed, was of importance in the rubber industry. He did not suggest that hydrocarbon oils, such as petroleum ether, could be recovered with anything like such a high efficiency as ether and alcohol, except possibly with a rather extravagant use of cresol. Nevertheless, cresol transcended all other liquids which he had tried except melted phenol, which was interesting in connexion with Dr. Ormandy's remarks. Phenol had a greater heat of reaction than cresol with ether. Mixtures of phenol and cresol, liquid at ordinary temperatures, had been considered, but for winter temperatures so much cresol was needed that no useful improvement would be gained. There were other matters, such as the slight volatility of cresol itself, which had to be taken into account, as had been found to be the case at Gretna. Other points which had been studied very thoroughly at Gretna included the increase in the viscosity of cresol when used in metal vessels. He understood that steel was almost the only metal which could be used with cresol; for instance, in one plant, in which lead-lined scrubbers had been used they were corroded through in a week, but these and various other questions had not come within his province. Nevertheless, they could rest assured that, of all the liquids hitherto examined, cresol appeared in general to be by far the best.

Meeting held at Burlington House on Feb. 7, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE EROSION OF BRONZE PROPELLERS.

BY O. SILBERRAD, PH.D.

During the twelve years, 1908—1920, which these researches have occupied, notices of the principal conclusions arrived at in the early part of the work have from time to time appeared in print,[1] but although the β type of alloy to which they led has been universally adopted throughout the world for the manufacture of high-speed propellers, nevertheless no detailed or succinct record of the work has heretofore been made public; it is therefore with this object in view that the following account is now presented.

Prior to 1906 all observed cases of deterioration of ships' propellers appear to have been traceable to chemical corrosion and, with the possible exception of a few isolated cases, to have been confined to cast-iron or steel propellers. Soon after this date, however, numerous instances of deterioration occurred in bronze propellers of high-speed ships. In appearance this new form of deterioration bore a superficial resemblance to the corrosion above referred to, and it appears to have been generally assumed that chemical action was at the root of the trouble in both cases. As a result it was not until 1908, when these researches were commenced, that the phenomenon was submitted to systematic investigation.

In the meantime, as progress in marine engineering rendered greater velocities in ships practicable, the seriousness of the position became more acute, until this deterioration of the propellers was becoming the limiting factor to further developments in the direction of speed; thus, in the case of the Cunard liners, Mauretania and Lusitania, the first set of propellers was practically destroyed after three months' running (see figs. 1—3), whilst high-speed torpedo destroyers have been known to show serious erosion in a single trial run at full speed (see fig. 4). At this juncture Messrs. Charles and P. R. Parsons, of The Manganese Bronze and Brass Co., Ltd., instigated the present researches which have resulted in the discovery of the erosion-resisting alloys that are now used throughout the world for the propellers of high-speed ships[2] and, incidentally, in proving that the deterioration is due to mechanical erosion brought about by a combination of frictional rub with "the action of water broken by evacuated spaces in which no air is present."[3]

Quite recently this subject has again been brought into prominence through the investigations of a sub-committee of the Board of Inventions and Research.[4] The conclusions arrived at by this Committee on the whole confirm the author's earlier observations that the deterioration is primily due to mechanical causes. As regards chemical action, the Committee observe that there is no evidence of this,[5] which is also in accord with the author's investigations.[6] On the other hand, although the conclusions of the Committee as regards the mechanical nature of the deterioration entirely confirm the researches of the author and, indeed, throw considerable additional light on the mechanism of that part of erosion due to the collapse of evacuated spaces, nevertheless their views as to the precise nature of the underlying causes are not, in the opinion of the author, quite in accord with the observed phenomena. Prior to 1912 the author's experiments led him to the conclusion, firstly, that erosion proper is a purely mechanical effect, and, secondly, that this mechanical action was brought about by water broken by intervening evacuated spaces, or vacuum bubbles,[7] coupled with frictional rub of said water.[8]

The Committee would appear rather to hold the view that the former of these two agencies, which they aptly refer to as "water-hammer action," is operative almost to the exclusion of frictional rub: they appear to have arrived at this conclusion (a) because erosion does not appear to be the invariable result of velocity, although admittedly it is more likely to occur under the conditions pertaining in high-speed ships; (b) because erosion is observed in local patches, sometimes quite near the roots of the blades. The fact that the tips of high-speed propellers are frequently not eroded at all merely indicates that the frictional rub at these points alone is not sufficient to cause erosion. The distribution and nature of the observed eroded areas renders it perfectly obvious that the frictional rub of the water is, as a rule, only active when operating on metal which has been damaged through the collapse of the vacuum bubbles referred to above, or where local pressure and velocity are excessive.

[6] Editorial on the author's work (*Engineering* 1912, p. 33). "An examination of the damaged propellers showed that the eating away was quite different to ordinary corrosion in still water. In that case if dissolution takes place, it is selective in character, the zinc being dissolved, a spongy mass richer in copper being left. No similar phenomena were apparent in the case of the eroded blades. Analysis showed no copper enrichment; the results agreed with the intended composition with extraordinary accuracy."

[7] This apt expression for the evacuated spaces was first used by Mr. Stromeyer: *Trans. Naval Architects*, 1919, 242.

[8] *Engineering*, 1912, 34. Editorial on propeller erosion. "Dr. Silberrad holds that erosion proper is a purely mechanical effect. . . . The area attacked" (in the case of the Mauretania) "is near the hub. This was of large size, and it seems probable that there was a certain centrifugal action causing a reduction of pressure, and this region of reduced pressure was marked by the erosion. Dr. Silberrad considers that cavitation might occur and in consequence, water broken by intervening evacuated spaces with no air present."

That frictional rub under certain conditions can alone bring about erosion was demonstrated by the author's jet experiments carried on in 1911,[9] and has, in the author's opinion, been further confirmed by the experiments of the Committee themselves, which showed that not only did jets of water produce an etching effect on the surface of propeller metals,[10] but also that rods inserted in jets were "eroded away to a greater or less degree in parts . . . the general conclusion was that the degree of etching of these rods depended chiefly upon the duration of the experiment and the velocity of the water,"[11] and although the Committee's experiments were conducted with sea water, it is nevertheless fairly obvious that this action is mechanical and not chemical, for, firstly, when manganese bronze is subjected to the action of sea water it becomes tarnished all over and seldom shows any signs of etching; and, secondly, the author's original jet experiments,[12] which produced a similar effect, were conducted with fresh water which had been recently distilled, and which is without chemical action on manganese bronze. Hence it appears justifiable to conclude in cases where the whole of the driving face of large propellers is bright and has the appearance of being etched all over when the ship is dry-docked immediately after running at full speed, that this etching effect is in reality erosion, due very largely, if not entirely, to frictional rub. Indeed, referring to this subject in his report to the Committee, Prof. Carpenter says it "may be due to the mechanical wearing away of the metal caused by the rapid flow of water over the surface of the blade."[13] That it has not in general an appearance identical with the more serious patches of erosion is doubtless due to the fact that the latter is brought about by this frictional rub in combination with the passage of water broken by intervening evacuated spaces or vacuum bubbles. The difference in appearance, however, seems to be rather a question of degree: thus, where the rush of water has been extremely violent—as, for example, in the case of the spindle of high-pressure hydraulic valves, the seating of which has become so worn as to permit of the continuous passage of water (see fig. 5)—an effect is produced almost identical with that observed in the case of propellers (figs. 1—3).

As regards the influence of structure, the Committee appear to be of the opinion that there is no evidence showing "any connexion between the structure of a metal and the distribution of erosion."[14] It is true that the precise area attacked is determined by outside influences; nevertheless, the portion of the alloy destroyed is determined largely by the structure of the metal; indeed, frequently the substitution of an alloy of the right structure renders the propeller capable of withstanding these outside eroding influences altogether. It should, however, be observed that the Committee's investigations on this subject appear to have been confined to the examination of a propeller constructed of one of the erosion-resisting alloys which were the outcome of the earlier part of these researches, namely, an alloy of essentially β structure. Further, it should be observed that Professor Carpenter's work on this point does not in fact quite bear out the Committee's conclusion. Thus, he reports "that of these two constituents" (viz., α and β crystals) "it may be predicted that α will be the more easily deformed of the two," and he actually finds two instances of such deformed α crystals. He also shows that a direct application of mechanical force establishes that the β crystals are not subject to distortion and that "they show that any considerable accumulation of deformed α at the surface is not to be expected on account of the small amount present" (in the alloy of the new erosion-resisting type examined by him), "and, further, that such deformation must be confined to α which is not entirely surrounded by β."[15] It was precisely similar observations[16] which led the author in 1908 to recommend the use of an alloy of primarily β structure in the case of the "Mauretania" and subsequently for the manufacture of propellers liable to be subjected to erosive influences in general[17]; and, as Sir William Ramsay observed,[18] "since this alloy has been universally adopted for such purposes it must be admitted that these observations were fairly in accord with facts."

In reviewing the work of the Committee in general as set forth in Sir Charles Parsons and Mr. S. Cook's paper, though it must be admitted that much of the work merely confirms facts which have been generally accepted and utilised in the trade, the Committee have nevertheless rendered a signal service in throwing so much light on the enormous forces operative when evacuated spaces collapse under water, thus very conclusively confirming the phenomena previously observed by the author. It is, however, impossible to agree with their observation that the type of alloy used is unimportant, or that all tendency for high-speed propellers to become eroded can be eliminated through amending the design.[19] In the first place, the Committee only appear to have examined propellers cast of the present erosion-resisting alloys which are the outcome of the author's researches; and, further, erosion is frequently traceable to damage done to the edges of the propellers through contact with steel hawsers, wreckage, etc., namely, causes in no way bound up with the question of design. But even apart from such considerations, the difficulty in arriving at "the right design and position of propeller" for high-speed ships is such that it is obviously desirable to adopt an alloy possessed of as high a specific resistance to erosion as possible; indeed, without some such alloy it seems improbable that anything approaching the present speeds could ever have been reached.

I. *Investigation into the causes of deterioration.*

Chemical examination.—At the commencement of this investigation the idea that the deterioration in question was due to chemical action was so generally prevalent that it was difficult to approach the subject with a truly open mind; a careful chemical examination of the damaged surfaces in a large number of cases, however, entirely failed to supply any evidence of chemical action; there was no sign of any concentration of copper or deficiency of zinc, as would be expected in the event of such severe deterioration being the result of chemical action. As regards composition the alloy proved to be the ordinary high-tension manganese bronze in all the early cases examined; the only possible indication of chemical action at all lay in the observation that the crystalline structure of pro-

[17] Parsons & Silberrad, Eng. Pat. 232 of 1910. In this connexion it is interesting to note that two years later, viz., in 1912, the Gewerkschaft Rubelbronze of Berlin recommended the use of an alloy of β structure as being suitable for "propellers of battleships and other high class steamships," alleging that this bronze was identical with the "bronze C" manufactured by them in 1908. It should, however, be observed that the physical properties of the alloy recommended by them in 1912 do not coincide with those published in respect of their alloy of 1908, with which the alloy they subsequently recommended was supposed to be identical; and, further, that on the strength of this the Gewerkschaft Rubelbronze of Berlin attacked the Austrian equivalent of this patent (Austrian Pat. 53094 of 1910 by Parsons & Silberrad), but were unsuccessful in their suit in spite of the fact that this country was at war with Austria at the time.
[18] Sir William Ramsay, *Engineering*, Nov. 21, 1913.
[19] *Trans. Inst. Naval Architects*, 1919, 247.

pellers was frequently clearly observable over considerable areas, the surface being bright and having the appearance of recent etching when the propellers first come out of the water. It seems probable, however, that this etching also is due to mechanical erosion, for the above phenomenon was only noticeable providing the ship had been running at full speed immediately before dry-docking; the propellers were always observed to be tarnished all over if she had been at rest two or three days previously. Experiments with a view to reproducing this condition were therefore undertaken, and it was found that a precisely similar appearance can be produced by subjecting the alloy to the action of a jet of high-pressure water, whereas on immersing a piece of manganese bronze in sea water it became tarnished rather than etched. Fig. 6 represents a specimen which has been subjected to such a high-pressure jet; the best results were obtained with small direct jets constructed of steel and supplied with water from inverted steel cylinders into which nitrogen at 2000 lb. per sq. in. was forced by means of a three-stage compressor, the water being covered with a layer of B.P. petroleum to prevent solution of the nitrogen.

any electric leak detectable throughout any of the ships examined.

The suggestion made by Mr. Ramsay[25] that local electric disturbances set up through mechanical stresses might be the cause of the deterioration led to the examination of the behaviour of a sample of this same alloy when submitted to a variable stress under sea water. This experiment was carried out by submerging a bar $8 \times \frac{1}{2} \times \frac{1}{2}$ in. in sea water, one end of the bar being held rigidly and the other end attached to an eccentric making 4 strokes of 1 in. per minute. The results are incorporated in Table I., below, from which it will be observed that the alteration in weight due to corrosion in this case is only very slightly greater than that suffered by a similar bar of this alloy not under stress; and that in both cases the loss is entirely negligible as a factor in dealing with the severe type of deterioration under consideration.

Physical examination.—Although the above observations were sufficient to constitute fairly conclusive evidence that the deterioration was not due to chemical or galvanic action, they are nevertheless all of a negative rather than a positive nature; it was therefore decided to make full examination

In order to investigate further the extent to which chemical action plays a part, a sample of manganese bronze cut from one of the wing propellers of the s.s. "Mauretania" was submitted to the action of sea water, the alteration in weight per sq. m. exposed being recorded from day to day. The results are given in Table I., from which it will be observed that the average loss of weight of this particular bronze was 0·28 g. per sq. m. per day. The maximum depth to which the deterioration had reached in the particular propeller from which this sample was cut was 2½ in., from which it will be observed that it would take over 5000 years[24] to effect the observed deterioration by chemical corrosion; and since the deterioration in question was caused in 3 months it becomes self-evident that chemical corrosion is a negligible factor in the deterioration under consideration.

Galvanic action.—No evidence of galvanic action being a factor could be obtained. In all the most pronounced cases examined the protecting zinc plates in the neighbourhood of each of the propellers were in perfectly normal condition, nor was there

[24] 10,000 × 2·5 × 2·54 × 8·821 ÷ 0·28 × 365·25 = 5169·8 years.
[25] *Engineering*, May 24, 1912.

of a series of damaged propellers with a view to gaining a further insight into the nature of the operating causes.

Micro-examination of the eroded surfaces of a large number of propellers revealed distinct evidence of deformed α crystals; this was confirmed by cutting pieces from the eroded portions, embedding them in soft solder, and examining them after sectioning and polishing.

In the early days of these researches the propellers examined possessed the normal structure of manganese bronze, namely, essentially an α-structure. In general these samples were remarkably similar and showed deformed α crystals wherever these predominated; cases were also observed of part of the alloy having been washed away, leaving protruding crystals, most of which showed varying degrees of deformation. In a few isolated cases where the proportion of zinc in the alloy had been allowed to get a little above normal the alloy assumed a mixed α and β structure; in these cases it was observed that the β crystals stood up to the erosion remarkably well, whereas the α crystals, where they were not embedded in β, had either been crushed, broken off, or else washed right away. A typical example of such an eroded

edge is illustrated in fig. 2, the propellers in question having been scrapped after running less than three months on account of erosion. In this connexion fig. 3 is also interesting as illustrating an a crystal which has been deformed and broken at the point.

propeller blades. A thorough examination of a very large number of propellers, however, rendered it possible to arrive at a series of generalisations as to the areas attacked and to classify these into three types, each type being traceable to special conditions productive of currents of water, broken by evacuated cavities, or vacuum bubbles, impinging on the areas eroded.

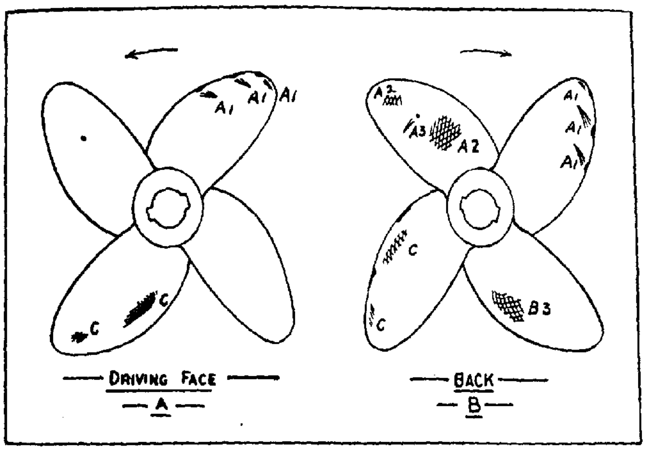

FIG. 7.—(1/100 full size.)
Diagram of 4-bladed propeller showing various types of erosion.

It will be observed therefore that micro-examination of eroded bronze revealed distinct evidence as to the deterioration being mechanical in origin, and also as to the superiority of β crystals in their capacity to withstand this erosion. These conclusions were subsequently very fully confirmed by taking small samples of a very large series of propellers as they were cast, submitting these samples to micro-examination and subsequently inspecting the propellers from time to time as they developed any defect in use. In this way so close a connexion between the microstructure and the capacity to withstand erosion under any given conditions was established that it became possible by merely studying the microstructure of any given propeller to give to it a relative figure of merit which was closely indicative of its capacity to withstand erosion.

Macro-examination.—An exhaustive macro-examination of a large number of eroded propellers was next entered upon, which established, in the first place, that dirt in the castings played little or no part as a determining factor, either as to the position or degree of the erosion produced. In this connexion many cases of unsound castings were examined, and although instances remarkably similar to erosion were found, when propellers having such defects were put to work the cavities in question showed no signs of developing into erosion; indeed, if anything, they assumed a slightly smoother appearance.

In the second place, it was noted that eroded propellers belonged to one of two classes—they were either relatively small propellers running at a high speed (*i.e.*, 600—800 r.p.m.), as in the case of torpedo destroyers; or else they were large propellers transmitting great power, as in the case of battleships or fast liners, as, for example, the "Mauretania," the "Lusitania," the "La France," and the "Imperator."

As regards the areas eroded in the different propellers examined, these were most varied and in the first instance most perplexing, erosion being observed on the boss, base, centre, and edges of the

Classification of the various types of erosion.

Type A. Erosion due to damage done to the propeller.

Erosion of this type divides itself under three heads:—

Type A. 1. Erosion due to damage done to the leading edge.—Whenever the leading edge of a high-speed propeller is bent or deformed an eroded area results on that side of the blade towards which the damaged edge has been deflected. Thus the erosion starting from damage of this sort will be found on the driving face if the leading edge has been bent towards that face (see fig. 7 A), whereas if the damage done to the leading edge has caused the metal to become bent backwards, the erosion will appear on the back of the propeller (see fig. 7 B). Frequently these areas of erosion are deep and very clearly defined, often tailing off in comet-shaped grooves. It thus becomes evident that the contributing conditions which lead to erosion of this type are as follows:—

The leading edge being distorted leaves a trail of water broken with evacuated spaces starting from the distortion on the side towards which the blade has been deflected; as this current of broken water sweeps over the blade the vacuum bubbles therein collapse, and the combined frictional rub and water-hammer action so produced cause the erosion observed. As is to be expected, erosion of this type is generally situated on an arc described from the centre of the propeller and passing through the damaged edge; where exceptions have been observed these appear to be due to deflecting currents influencing the flow of the broken water caused by the damaged edge.

Type A. 2. Erosion due to damage done to the following edge.—Deformation of the following edge of a blade is liable to cause a stream of broken water to impinge on the back of the next blade of the same propeller (fig. 7 B). Erosion of this type occasion-

ally covers a considerable area, but is seldom deep; its origin is attributable to causes precisely analogous to those which bring about the A. 1 variety—the distorted following edge leaves a trail of water broken with evacuated spaces which impinges on the back of the next blade; the current in this case is generally more disturbed and, as a consequence, the erosion is less intense but covers a greater area.

Type A. 3. *Erosion due to holes in the propeller* (as when the plug comes out of the shackle hole). Under these circumstances a comet-shaped area of erosion results on the back of the blade (fig. 7 B), the eroded area being on an arc described from the centre of the propeller and passing through the hole. A little consideration will render it obvious that erosion of this type is due to the following causes:—

The water on the driving face of the propeller being under pressure rushes through the shackle hole, thus taking up the rotary movement of the propeller; the jet of water so produced strikes the relatively stationary water behind the propeller, thus causing cavitation in the form of an evacuated space round the jet; the broken water so produced is subsequently swept over the back of the propeller on which the vacuum bubbles collapse, causing the comet-shaped eroded area invariably observed when the plug comes out of the shackle hole of a high-speed propeller.

Type B. *Erosion due to disturbances caused by the propeller itself.*

Three distinct types of erosion arising from disturbances set up by the propeller itself have been observed, namely—

Type B. 1. *Erosion due to high number of revolutions made by the propeller.*—When a propeller of any given design is running at too high a speed erosion appears at or near the root of the driving face (fig. 8). In these cases it would seem that erosion is due to the centrifugal action caused by such rapid revolution, as a result of which water, broken by evacuated spaces, is whirled outwards into areas of greater pressure, thus causing the vacuum bubbles to collapse on the surface of the blade near the root.

B. 2. *Erosion due to stream lines caused by the following edge of the preceding propeller.*—Erosion of this type generally appears as a deep cut on the boss near the back of the blade following, and seems to be confined to propellers with very wide blades having a relatively small diameter and making a fairly high number of r.p.m. (See Fig. 9.)

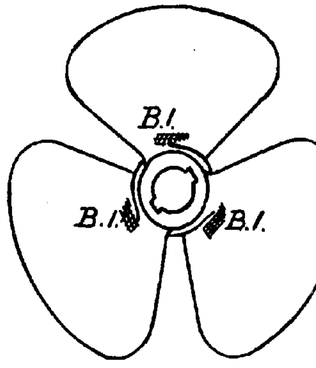

FIG. 8.—(1/25 full size.)
Diagram of 3-bladed propeller showing B1 erosion on driving face.

Type B. 3. *Erosion due to backwash from the sides of the ship.*—This is liable to occur where the wing propellers have insufficient clearance, especially if they turn inwards; in this case the backwash causes broken water to be thrown on to the propellers, thus producing severe erosion (fig. 7 B). Figure 1 illustrates an extreme case of this class, in which erosion to the depth of 2½ in. was caused

TABLE II.

Classification of causes of erosion.

Class.	Cause.	Position and appearance.	Illustration.	Remedy.
		A.—Erosion due to damage done to propeller.

in three months. As regards position, this type of erosion is generally to be found on the back of the blade, though naturally it varies with the precise position of the seat of the cause.

Type C. *Erosion due to passage of some body forward of the propeller,* which causes a stream of water broken by evacuated spaces to impinge on the propellers. Erosion of this type is generally due to one of the following causes:—

Type C. 1. Stream lines of water broken by evacuated spaces produced by another propeller forward of the propeller in question.

Type C. 2. Stream lines of water broken by evacuated spaces produced by "A brackets" situated forward of the propeller eroded.

Type C. 3. Stream lines of water broken by evacuated spaces produced by the ship itself.

Such erosion generally appears on both sides of the propeller and varies enormously both in shape and intensity. It occurs on the back whenever a stream of water broken by evacuated cavities impinges on the propeller and is due to the collapse of these evacuated spaces on striking the surface in question (fig. 6B). Similar erosion on the driving face is obviously due to the same cause; the streams of broken water on being cut by the propellers suddenly enter an area of high pressures with the result that the evacuated spaces collapse on the driving face at a distance from the leading edge dependent on the peripheral velocity of the propeller at the point of cutting. As a general rule erosion due to this cause will therefore be found on both sides of the propeller, but is likely to be more intense on the driving face than on the back.

For the sake of convenience in reference these various types of erosion have been classified in Table II. under the causes to which they are attributable.

PART II.—*Production of propeller alloys possessing relatively high specific resistance to erosion.*

From the investigations described above the following conclusions may be drawn respecting the nature of this deterioration:—

1. Chemical action is a negligible factor.

quently collapse on the propeller blades, both of which conditions, it will be observed, are more liable to arise in high-speed ships or propellers moving at a high velocity.

It has also been established above that where alloys containing α crystals are exposed to this action, these α crystals are liable to deformation unless they are wholly embedded in β crystals, from which it would appear that a bronze composed essentially of a β structure is best calculated to withstand the deterioration under consideration.

At the date when these researches were commenced, however (1908), β alloys consisting essentially of copper and zinc were regarded as being mechanically unsound; this research therefore next turned upon the problem of discovering suitable additions to copper-zinc alloys of the manganese bronze type which would change them from essentially α alloys to those of β structure without impairing their physical properties in any way. In carrying out this part of the investigation use was made of Guillet's work on complex brasses,[22] wherein he showed that one part of zinc may be replaced by an equivalent quantity of any of a series of certain other metals without affecting the structure of the original copper-zinc alloy. These "equivalents" must not in any way be confounded with the atomic weights of the metals, to which they do not appear to bear any very simple relationship. Thus, 1 part of zinc is equivalent to aluminium 0·16 part, iron 1·1, manganese 2·0, cadmium 1·0, lead 1·0, silicon 0·1, or tin 0·5 part. Making use of these equivalents a large series of alloys possessed of β structure was made; in each case part of a 300-lb. charge was cast in sand and part in chill; test pieces were cut from each, and the alloy thoroughly examined both mechanically and microscopically. As this paper deals essentially with erosion and does not pretend to go into metallurgical problems it is not proposed to give these researches in detail; the following table, however, sets forth a few of the more important results which led to the production of a mechanically sound alloy of β structure, and gives the composition and properties of a series of alloys representative of each step in the research.

TABLE III.
Development of bronzes.

	Standard manganese bronze for comparison				33·0	17·0	20	120

All these alloys possessed a homogeneous β-structure with the exception of the standard manganese bronze, which showed strong α-crystallisation. The above figures show that tin in appreciable quantity appears to act very detrimentally on β-alloys. The marked improvement in physical properties caused by the introduction of manganese should be noted, though the presence of as much as 9% renders the alloy troublesome in the foundry. The chief effect of aluminium appears to be to raise the elastic limit. The alloy containing Al, Mn, and Fe may be regarded as the parent of the present erosion-resisting bronzes. The first propellers made of it were cast by The Manganese Bronze & Brass Co. in 1908, for the *Mauretania*. The first alloy of the type of standard manganese bronze was introduced by Mr. P. M. Parsons of The Manganese Bronze & Brass Co. in 1876.

2. Galvanic action does not appear to come into play at all.

3. The presence of dirt in the castings has only a slight detrimental effect.

4. The true cause of the deterioration is mechanical and is therefore properly termed erosion, the determining factors being:—

(*a*) The frictional rub of the water.

(*b*) The impinging on the propeller blades of water broken with evacuated spaces which subse-

From these results it will be observed that although a copper-zinc brass of purely β structure is not a satisfactory alloy, nevertheless alloys quite equal in mechanical properties to the old-established α bronzes can be produced by introducing small quantities of aluminium, manganese, iron, etc. Having thus established the practicability of producing improved erosion-resisting alloys of this

[22] Guillet, *Rev. de Mét.*, 1906, 159.

type, their further development and application followed as a matter of course, and such alloys are now used throughout the world for the manufacture of propellers for high-speed ships. Photomicrographs of some of these alloys are given in figs. 10—15. In No. 10 (tensile strength 34 tons, elastic limit 17 tons per sq. in., elongation 25%) the α crystals are sufficiently protected to render the alloy immune from any but the most severe erosive influences to which marine propellers are subject, whilst the α crystals present render the alloy much more easily repaired or worked than a homogeneous β alloy. Similar remarks apply to a lesser extent to No. 11 (t.s. 30, el. lim. 15·5, elong., 33%), which although essentially an α bronze still has sufficient β crystallisation for protective purposes where the eroding influences are not excessive. Nos. 12 and 13 (t.s. 40—42, el. lim. 20, elong, 17—25%) represent a homogeneous β solution and have the highest possible specific resistance to erosion. No. 14 (t.s. 36—38, el. lim. 18·5, elong. 30—35%), and No. 15 (t.s. 33—35, el. lim. 17·5, elong. 25—30%) have α crystals embedded in β and are excellent all-round propeller alloys. It is noteworthy that although the former of these alloys contains a higher percentage of zinc, it is even less subject to corrosion than manganese bronze (see Table I.); it is suggested that this may be due to the extreme homogeneity of the alloy, which is a practically pure β solution.

The first ship equipped with propellers cast of an alloy of the new type was the "Mauretania." It will be remembered that in three months this ship wore out her first set of propellers, which were cast of the old type of bronze (see fig. 1); the propellers of the new alloy were fitted in January, 1909, and it is interesting to note that the Surveyor for the Germanische Lloyd, on inspecting these new propellers after they had run for six months—*i.e.*, twice as long as the original ones of normal manganese bronze lasted—reported that they were in perfect condition, there was no sign of wasting or erosion, and the surface appeared to be as good in every way as when the castings were first made.

In conclusion I desire to express my thanks to Mr. P. R. Parsons for his most skilful co-operation throughout these researches. My thanks are also due to Sir Phillip Watts, K.C.B., F.R.S., for his valued advice on numerous occasions, to Dr. Desch for his assistance in connexion with the photo-micrographic records, to Mr. A. T. Quelch, O.B.E., Mr. F. G. Martin, The Manganese Bronze and Brass Co., Ltd., Messrs. J. Stone and Co., Messrs. Billington and Newton, Ltd., the Superintendents of the various Admiralty Dockyards, The Cunard Co., Ltd., Messrs. Harland and Wolff, Messrs. Cammell, Laird and Co., Ltd., and Messrs. Alfred Holt and Co., Ltd., for the facilities afforded me on all occasions during the last twelve years when inspecting eroded propellers and otherwise pursuing these investigations.

Discussion.

Mr. A. T. Quelch said that during the past thirteen years he had made 16,000 or 17,000 tons of bronze propellers and propeller blades; a large number of these had been made with the β-alloys referred to in the paper, and he could concur with the author that the erosion was purely mechanical. He had had occasion to examine very many high-speed propellers. In the case of the "Swift"—a very fast scout type of destroyer, designed for 36 knots—difficulty had been found in keeping up the speed for the six hours full-speed trials. Experiments with the design of the propellers had been started. Altogether 26 propellers had been made for that ship, and examination of these had revealed the very curious way in which, as the design was altered, the area of the eroded part moved about, a fact which proved that the erosion was purely mechanical. In that particular case the expanded area of the three blades was actually greater than the disc area, which fact introduced that peculiar cause of erosion, the interference of one blade with another, which produced a deep cut on the back. During the war the greater number of the destroyers built had been built of the geared turbine type, giving reduced speed of the propellers, in the hope that it would put an end to erosion troubles. Soon afterwards, however, serious erosion had been reported to be taking place on the Bruce-Douglas type of destroyer leader. Examination had shown that the greater proportion of this so-called erosion was dirt washed out of the propeller, due to a great extent to the design of the propeller. Unfortunately, the engineer often did not consider whether the designs were good or bad from the founder's point of view. In this particular case the propellers were of such a large surface, coupled with a short boss, that both the leading and following edges of the blades overlapped the top and bottom of the boss. Propellers were cast with the driving face downwards, so that the following edge of the blade was considerably below the level of the bottom of the boss. The gate was put into the bottom of the boss so that the first flow of metal which entered the boss had to run down hill, and there was a considerable disturbance of this metal by eddies etc., and the production of a large amount of oxide. The section of the blade of those particular propellers, about six inches from the tip, was about 6 ft. long by about 1¼ in. thick, so that the dirt had not much chance to get away. The only serious erosion in this particular case was on the back of the blade, almost on the fillet, and it was due, in his opinion, to the very badly designed A bracket. The section of this A bracket was very square, and, in addition, there was a lubricator in the angle of the A bracket, by the boss, which had the effect of throwing a jet of disturbed water on to the propeller, with the result that grooves were eroded in the blade to the extent of 1¼ in. deep.

He would like to ask the author as to the size of crystals in the β structure which could be produced by adding various metals, *e.g.*, Al, Mn, Fe, to the ordinary copper-zinc alloy. There was considerable variation in the size of the crystals, although their general type was the same, and this might have a very considerable influence on the mechanical properties. Whereas quite favourable results might be obtained in an ordinary tensile test piece, when the alloy was exposed to the stresses obtaining in the case of a propeller, in which there was considerable variation in stress and reversals of stress at different times, there might be failure in the material in resisting fatigue, which was most important with any running machinery. He had had very little trouble with the β-alloys, in which he had been particularly interested, but he believed certain troubles had occurred in propellers using alloys of somewhat similar structure where, for no apparent reason, the whole of the blade had broken off. He had recently manufactured some large propellers for Japanese battleships, of turbadium, which weighed, in their finished state, 13¼ tons each. One test-piece had been taken from each blade and one from the boss. The elastic limit of all the test pieces actually taken from the first of these propellers was 21 tons, the ultimate strength averaged 41 tons, and the average elongation 20%, which was a good result with a copper-zinc alloy. In the case of these alloys there was not the breakdown at the yield point that there was in steel, but the elastic limit was defined as such a stress as would produce a permanent set of 0·003 in. Since making these propellers he had made a smaller propeller of a β-type of alloy, but arrived at in a different manner from turbadium, the object being to get a little

more stretch or ductility in the alloy. In this case the test piece taken from the propeller showed an elastic limit of 18 tons, an ultimate strength of 38 tons, and 27% elongation, with a cold bend test on a 1 in. square bar between 12 in. points of support of over 90° without fracture. With regard to the propellers of the "Mauretania" and "Lusitania," he thought they were inclined to give a little too much credit to the alloy. The original propellers on both these vessels had been of the built-up type, *i.e.*, the blades had been cast separately and bolted on to the boss, so that the external conditions would be rather worse than in the solid propeller. The design of solid propellers eventually adopted was very different, and it was a little difficult when comparing the results in resisting erosion to say how much credit was due to the alloy and how much to the altered design of the propeller. In the case of the Tribal class of destroyers built about 1910, propellers had been made of exactly the same design, some of ordinary manganese bronze and some of turbadium, and the great advantage in having the β-type of alloy, from the point of view of resisting erosion, had been evident. There was still some slight erosion, but it was very difficult to produce an alloy which would have the necessary mechanical properties to withstand the arduous service of a propeller in constant work, where there were very many stresses introduced, especially in the case of light-draught boats, like destroyers, and at the same time be the best structure to resist erosion. In the case of the "Hood," for instance, the finished weight of each propeller was about 19½ tons, and in the actual manufacture 30 tons of metal had to be dealt with. It would therefore be realised what a very big problem it was to produce an alloy which would meet all the mechanical tests and at the same time satisfy the very arduous conditions of propeller running and also offer a high resistance to erosion.

Mr. H. Talbot said that the author had brought out two points which, in his (the speaker's) opinion, were almost conclusive evidence in favour of the mechanical explanation. The first was the existence of what was practically a critical velocity of erosion, above which the rate of deterioration was especially marked; the second was the fact that equally resistant alloys contained metals of the same chemical family in proportions which had no connexion with their chemical combining weights.

Dr. Silberrad, in replying, said that he quite agreed with the observations respecting the influence of altering the shape and design of any given propeller on the position and nature of erosion produced; indeed the observance of such cases had contributed very materially to the classification of the different types of erosion. With regard to the tendency of homogeneous β-alloys to solidify in large crystals, very little seemed at present to be known about the particular combinations which influenced this. Cases where alloys on solidification formed crystals as much as two inches long and several pounds weight had come before his notice, and in such cases, as a rule, a very slight alteration in composition had been found to cause the alloy entirely to change its properties in this respect. In that case the alloy was very easily broken, not with one single hit, but when subjected to continuous vibration. One of his exhibits was a sample from a propeller made of an alloy which showed this tendency; it had broken off short in use. By taking Guillet's equivalents it was possible to predict the influence of various metals on the alloy to some extent and thus obtain satisfactory mechanical results. He was never able, however, to get any idea at all as to what effect an alteration in composition would have on the tendency to form large crystals. That appeared to resolve itself into a question of trial and error, and the experiments ran into hundreds before the final results were obtained. But actual experience had proved that the crystals should not be too large, and further, the presence of small α crystals which could be regarded as embedded in the β solid solution was advantageous. Such an alloy would resist erosion almost as well as a pure β alloy and at the same time had the advantages of an α alloy, which was able to stand fatigue better. Moreover, this alloy of mixed structure could be handled much better in the foundry. Propellers in use get knocked against dock gates and hawsers, and thus not infrequently suffered severe damage, to repair which was much more troublesome in a pure β alloy than in the case of an alloy of mixed α β structure.

Another difficulty which took a good deal of overcoming was that of determining in what proportions the various ingredients for any given alloy should be taken in order to produce the desired composition when making comparatively large castings; for in operations of the type here dealt with it was no uncommon thing to have to run 20—30 tons of bronze at once, and when it was realised that alloys of this type alter in composition through loss of zinc, oxidation of manganese, and elimination of aluminium the whole time that they were in the reverberatory furnace and whenever they came into contact with air it would be seen that it was not easy so to adjust things as to arrive at an alloy varying not more than 0·1% or at most 0·2% in zinc, or an equivalent quantity of one of the substituting metals, which in the case of aluminium meant working to within ⅙th of 0·2%. But these difficulties, like most others, had given way before persistence. The problem had started by being apparently a fairly simple one, because he had expected merely to find chemical corrosion, but, as the paper showed, this was far from being the case, and the work had involved something like 12 years' research.

MR. J. H. HOSEASON IN THE CHAIR.

THE PREPARATION AND PROPERTIES OF 1.3.5-TRINITROBENZENE.

BY L. GUY RADCLIFFE, M.SC.TECH., AND ALAN A. POLLITT, M.SC.TECH.

The preparation of trinitrobenzenes presents interesting features in the light of the use of 1.3.5-trinitrobenzene as an explosive, but the literature relating to this subject is rather meagre, and for this reason the following research was undertaken.

Over a year ago experiments were made by one of us having for their object the determination of the conditions under which 1.3-dinitrobenzene could be further nitrated to form the trinitro derivative. In general, successful nitrations resulted in the production of the well-known 1.3.5-isomer, m.p. 121° C., but occasionally a trinitrobenzene of m.p. 61° C. was obtained, and this was at first thought to be the 1.2.4-compound described by Hepp (Annalen, 215, 362) and Lobry de Bruyn (Rec. Trav. Chim., 9, 190), though this compound is stated to melt at 57·5°.

It was soon found that this result could not be repeated at will, and numerous carefully conducted

* Publication of this paper was deferred at the request of the Ministry of Munitions.

experiments have so far entirely failed to establish the conditions under which the trinitrobenzene of m.p. 61° can be produced.

A study of the properties of this new trinitrobenzene has caused us to modify the opinion that it was 1.2.4-trinitrobenzene, inasmuch as it has been found possible to convert the compound melting at 61° into the ordinary symmetrical 1.3.5-trinitrobenzene, m.p. 121°, by several simple methods. The facts appear to favour the assumption that 1.3.5-trinitrobenzene can exist in two forms which differ widely in their melting points. Hepp (Annalen, **215**, 345) obtained 1.3.5-trinitrobenzene of m.p. 121°C. by heating 40 g. of 1.3-dinitrobenzene with a mixture of 300 g. of crystallised, fuming sulphuric acid and 120 g. of highly concentrated nitric acid (the exact strength of each is not stated), at first for one day at 80° C., and then for a further period of two days at 120°. The product was isolated by pouring the mixture into cold water, collecting the precipitate and washing it, first with water and then with dilute sodium carbonate solution, and finally crystallising the product from alcohol. Darst made the same substance by a very similar method.

Claus Becker (Ber., **16**, 1597) obtained 1.3.5-trinitrobenzene from 2.4.6-trinitrotoluene by heating it to 180° with fuming sulphuric acid, carbon dioxide being evolved during the process. Furthermore, the same trinitrotoluene can be oxidised to trinitrobenzoic acid, and this latter when heated with water yields trinitrobenzene.

Experimental.

Symmetrical or 1.3.5-*trinitrobenzene*.

In the earlier attempts to prepare this substance mixtures of fuming nitric acid and fuming sulphuric acid (up to 60% SO_3) were used, but even with a large excess of nitric acid and prolonged times of heating the dinitrobenzene was not nitrated. Further experiments were made with 100% nitric acid prepared by distilling a mixture of the 95% acid with 26% oleum. In the first of these nitrations 25 g. of dinitrobenzene was dissolved in 50 g. of oleum (26% SO_3) and 20 g. of nitric acid (approximately 1½ mols. excess) added in small quantities at a time, the flask being kept cool during the mixing. The mixture was then gently heated for three hours at 110° C. in a wide-necked flask over a small flame and appeared to boil gently. The product was poured into water, washed, and crystallised once from alcohol; it formed plates or leaflets, m.p. 61° C., which proved on analysis (*cf. infra*) to contain 99·8% of trinitrobenzene. A 30% yield of the new compound was obtained. On repeating this experiment, using larger quantities, the product melted at 121° C., and was the ordinary symmetrical trinitrobenzene. Another experiment was made in which the quantities were 50 g. of dinitrobenzene, 75 g. of nitric acid (100%), and 125 g. of oleum (26% SO_3). The two acids were mixed and heated to 110° C. and the powdered dinitrobenzene added gradually over a period of 1½ hours, after which the mixture was heated for a further 6½ hours at 110°—120° C. The product was isolated as usual, and on crystallising from alcohol plates of the *s*-trinitrobenzene, m.p. 121° C., were obtained; analysis indicated 100·2% of trinitrobenzene, the yield being 45% of the theoretical. In an attempt to increase the yield the same quantities as in the last experiment were used, and up to the completion of the addition of the dinitrobenzene the method of procedure was the same. At this point, however, a further quantity of mixed acids was added, consisting of 50 g. of oleum (26% SO_3) and 35 g. of the nitric acid; the mixture was maintained at 110°—120° C. for 6½ hours, as in the last experiment. A 56% yield of trinitrobenzene, m.p. 121°, resulted, its purity corresponding to 99·97% trinitrobenzene.

A repetition of this method, using oleum containing 60% of SO_3, in place of the 26% oleum, gave a yield of 60% of the usual *s*-trinitrobenzene; moreover, the time required was reduced to a total of 6 hours. In these experiments it was observed that a considerable quantity of the nitric acid was being lost by escaping from the flask, and therefore further nitrations were conducted under a reflux condenser, with the result that the loss of nitric acid was to a large extent prevented and the yield of *s*-trinitrobenzene slightly increased, *viz.*, to 63%. Another series of experiments was made in which the reflux condenser was used, and, in addition, the reacting mixture was mechanically stirred throughout the experiment. In the first stage 50 g. of dinitrobenzene, 75 g. of nitric acid (100%), and 125 g. of oleum (60% SO_3) were used, followed by 50 g. of oleum (60% SO_3) and 35 g. of nitric acid (100%); working under these conditions a yield of 71% of *s*-trinitrobenzene, m.p. 121°, was obtained.

It has not been found possible to improve on this yield, as the use of higher temperatures increases the risk of the reaction getting beyond control, and if the time of the nitration is increased beyond about eight hours there is a reduction in the yield due apparently to the oxidation of the nitro compound.

At this stage it will be convenient to describe the nitrations which yielded a trinitrobenzene of m.p. 61°. In one experiment 25 g. of dinitrobenzene was dissolved in 50 g. of 26% oleum, 20 g. of 100% nitric acid was slowly added, and the resulting mixture heated for three hours at 110°, the product isolated melted at 61°, and analysis showed it to be a pure trinitrobenzene. The experiment was repeated several times, in detail, but on each occasion the resulting compound was pure *s*-trinitrobenzene, m.p. 121°, and numerous other nitrations failed to give the compound of m.p. 61°.

In an attempt to effect an economy in the amount of nitric acid used in the above method 45 g. of dinitrobenzene was dissolved in 125 g. of oleum (26% SO_3), 20 g. of nitric acid (100%) added, and the mixture heated for three hours at 110°. On isolating the product, 26% of trinitrobenzene, m.p. 61°, purity 99·89%, was obtained, but again the repetition of the experiment gave the compound melting at 121°. These methods were frequently repeated and only very occasionally gave a product melting at 61°.

The failure to reproduce the experiment giving the compound melting at 61° seemed to indicate that some accidental trace of a catalyst might be causing its occasional formation, and therefore the effects of certain possible catalysts were tried, using the same conditions and quantities as in the two experiments just described.

First, a small quantity (0·5 g.) of flowers of sulphur was added to the nitration mixture, but beyond giving a slightly better yield of the ordinary *s*-trinitrobenzene it had no effect. Additions of ferric oxide, manganese dioxide, and urea produced no visible effect, the product being always the compound melting at 121°. It seemed possible that the presence of a trace of a reduced nitro compound, such as a nitraniline, might influence the nitration; to test this dinitrobenzene was mixed with a small quantity of sodium bisulphite before dissolving in the oleum, but this had no effect.

Whilst discussing the effect of catalysts the following interesting observation was made with regard to the effect of light on nitration. At a certain period it was found that the yields were not so good as usual. It was thought that as the windows of the laboratory had been darkened, at the request of the military authorities, by being covered with a blue wash, this subdued light might be the cause of the diminished yields, and when further nitrations were carried out in front of the

open window and in direct sunlight the original yields were obtained.

Another series of attempts was made to prepare the trinitrobenzene melting at 61° by using different strengths of oleum ranging from 20 to 60% SO_3, increasing the strength each time by 10% SO_3, the quantities being 25 g. of dinitrobenzene, 20 g. of nitric acid (100%), and 100 g. of oleum. In each experiment the nitric acid was added to the solution of dinitrobenzene in oleum and the mixture heated under a reflux condenser for three hours at 110°—120° C., with continuous mechanical stirring. The experiments gave without exception the variety melting at 121°, and the yields, though increasing with the strength of the oleum, varied very slightly. All manner of variations of these methods were tried, but in no case was the compound of m.p. 61° C. obtained. With the higher strengths of oleum it is not safe to exceed 120° C., especially when using a reflux condenser, as control over the reaction is very easily lost, but when using 20% or 30% oleum a temperature of 150° C. may be safely employed; furthermore, increasing the time beyond a certain limit causes loss of material and diminution in the yields.

It was now decided to alter still further the conditions of nitration, and with this object ordinary concentrated sulphuric acid (96% H_2SO_4) was used and sufficient phosphoric anhydride to take up the water in the sulphuric acid and also that produced during the nitration, with an additional 10% in excess of this theoretical amount: 37 g. of phosphoric anhydride was dissolved in 50 g. of sulphuric acid and 20 g. of dinitrobenzene dissolved in this mixture; the resulting solution was heated to 110° in an open flask and 12 g. of 100% nitric acid added from a tap funnel. After the addition of all the nitric acid the contents of the flask were heated for 3 hrs., attaining a maximum temperature of 150° C. after 1½ hrs., and maintaining this for the remainder of the time; no nitration occurred. A further 8 g. of nitric acid was added and the mixture again heated at 150° for a further 2 hrs.; a yield of 25% of *s*-trinitrobenzene, m.p. 121°, was obtained.

The experiment was repeated, starting with 20 g. of nitric acid instead of the 12 g. used at first in the previous attempt; the acid was added in three instalments of about equal volumes, the mixture being heated for 1 hr. to 130° after the first addition, for 1 hr. to 135° after the second, and for 3 hrs. to 150° C. after the third. This temperature was maintained for the remainder of the nitration. Although this method differs only slightly from the previous one, yet on isolating the product a yield of about 30% of the trinitrobenzene of m.p. 61° was obtained; analysis showed it to have a purity of 100·3%. During the nitration an oily layer formed, which solidified on cooling. It contained all the trinitrobenzene admixed with a very little unchanged dinitrobenzene, whilst the solid isolated from the residual mixed acid consisted almost entirely of unchanged dinitrobenzene. The formation of this oily layer has been observed in all the experiments in which phosphoric anhydride was used, no matter whether the compound produced melted at 121° or 61° C. This experiment was repeated exactly as detailed above, and again a 30% yield of the trinitrobenzene of m.p. 61° was obtained. Further repetitions, however, gave the compound of m.p. 121° C., and it has not been found possible to obtain further quantities of the compound of m.p. 61° C. by this method. No reason is advanced in explanation of these failures.

For the analysis of the products Knecht and Hibbert's method (see "New Reduction Methods in Volumetric Analysis." Longmans) was used, the trinitrobenzenes being dissolved in alcohol, reduced with titanous chloride solution, and the excess of the latter estimated by titration with iron alum.

The two varities of trinitrobenze are very similar in colour, being almost white, and both crystallise from alcohol in plates or leaflets made up of needles. Both forms are much less soluble than *m*-dinitrobenzene in alcohol; on crystallising the product isolated from a nitration, the first crop of crystals is almost pure trinitrobenzene, and by removing the second crop as soon as needles of dinitrobenzene begin to appear, a product is obtained which when once recrystallised is pure trinitrobenzene. This method of separation and purification is still easier if carbon tetrachloride is used instead of alcohol; the trinitrobenzenes are difficultly soluble in the former, whilst dinitrobenzene is comparatively very soluble. The trinitrobenzenes are easily soluble in ether and acetone and very soluble in benzene; both varieties are very slightly soluble in hot water and insoluble in cold water. The trinitrobenzenes dissolve in ammonia and caustic alkalis giving a deep red coloration, which is discharged by acids; they are not immediately affected by sodium carbonate or bicarbonate, but react slowly, producing a deep wine-coloured solution. The modification melting at 61° reacts with sodium bicarbonate in alcoholic solution much more slowly than does the variety melting at 121°. The colour is due to the formation of salts. By careful heating the ordinary form, m.p. 121°, may be sublimed, but it has not been found possible to sublime the variety of m.p. 61°.

With a view of establishing the constitution of the compound melting at 61°, the addition compounds of the two trinitrobenzenes with aniline were prepared. The molecular compound formed by adding aniline to the 1.2.4-trinitrobenzene, of m.p. 57·5°, is a red crystalline substance, m.p. 84°, whilst that obtained from 1.3.5-trinitrobenzene, of m.p. 121°, is also in the form of light red crystals of m.p. 124°. The aniline compound of the two trinitrobenzenes melting at 121° and 61°, as prepared by us, was made by adding aniline to each of the compounds and recrystallising the products from benzene; in both cases light red crystals were obtained, and from each variety the compound had the same melting point, viz., 124°. This remarkable result, wherein two compounds of widely different melting points gave an addition product with aniline having exactly the same melting point, dispersed the idea that the compound melting at 61° was 1.2.4-trinitrobenzene. On regenerating the trinitrobenzenes from the aniline-addition compounds by means of dilute hydrochloric acid each compound gave the same variety of trinitrobenzene, m.p. 121°. In this way the remarkable fact, that the trinitrobenzene melting at 61° could be converted into the well-known variety melting at 121°, was established. J. J. Sudborough (J. Chem. Soc., 1901, 522) has described the addition compounds of *s*-trinitrobenzene (m.p. 121°) with α- and β-naphthylamine and their resolution by means of acetyl chloride. We have prepared the naphthylamine compounds of the trinitrobenzenes of m.p. 121° and 61° C., and find that both these varieties give a compound with α-naphthylamine having m.p. 214° and with β-naphthylamine, m.p. 162°—the same figures as given by Sudborough. The trinitrobenzenes obtained by decomposition of these addition compounds melted at 121° C. in each case. These remarkable results lead to the conclusion that two forms of *s*-trinitrobenzene exist, and that the less stable form melts at 61° and is converted by simple reactions into the stable form, m.p. 121° C.

The conversion of the less stable into the more stable form was not accomplished by adding a crystal of the ordinary *s*-trinitrobenzene to a saturated alcoholic solution of the compound of m.p. 61°, but when equal volumes of the saturated solutions in alcohol of the two varieties were mixed and then fractionally crystallised only a compound of m.p. 121°—122° could be obtained. Heating the com-

pound of m.p. 61° for some time just above its melting point, either alone or in strong sulphuric acid solution, failed to bring about the conversion into the ordinary variety.

The molecular weights as determined by the Landsberger-Walker method, using acetone as solvent, were identical for both varieties, corresponding to a trinitrobenzene. The two varieties of trinitrobenzene were separately reduced with the calculated amount of strong titanous chloride solution and excess of hydrochloric acid in quantities sufficient to give a dinitroaniline from each of them; each variety yielded the same dinitro-aniline, in the form of bright yellow needles, m.p. 159°. Bader (Ber., 24, 1654) obtained 3.5-dinitro-aniline as yellow needles, m.p. 159°, by reducing 1.3.5-trinitrobenzene with ammonium sulphide; we have also reduced the two varieties of *s*-trinitrobenzene by the same method and obtained 3.5-dinitro-aniline, but the yield is not so good as that obtained by reduction with titanous chloride.

The nitrophenylenediamines and the triaminobenzenes were also prepared from each variety of the trinitrobenzene; the products appeared to be identical in each case.

From the above experiments there appears to be little doubt that *s*-trinitrobenzene can exist in two forms, and that one form is less stable than the other; it has not been found possible to control the conditions under which the less stable form is occasionally produced, but further investigations are in progress, and it is hoped that these points will soon be cleared up. In conclusion we desire to express our thanks to Mr. S. Medofski, B.Sc.,Tech., for his assistancce in some of the later parts of this work.

Addendum.

Since reading the above paper the behaviour of trinitrobenzene melting at 61° and 121°, respectively, has been determined according to the method suggested by N. V. Sidgwick (Chem. Soc. Trans., 1915, 107, 672), and we are indebted to S. Medofski, B.Sc.,Tech., for carrying out the experiments recorded below. Benzene was used as the solvent and its freezing point was determined, then the trinitrobenzene melting at 61° was added until the freezing point, which at first fell steadily, was constant. The trinitrobenzene melting at 121° was then added and the freezing point again determined. The depression of freezing point by trinitrobenzene of m.p. 61° was 2·474° (solubility 85·0 g. per litre), and the depression by the mixture of trinitrobenzenes, m.p. 61° and m.p. 121°, was 2·468°. It is evident, therefore, that the concentration of the solution has not increased by the addition of the compound melting at 121°, and that, according to Sidgwick, the forms are polymorphic.

THE RELATIVE ACTIVITY OF VARIOUS ALLOTROPIC FORMS OF SULPHUR TOWARDS CAOUTCHOUC.

BY D. F. TWISS AND F. THOMAS.

The investigations in recent years of the allotropic forms of sulphur capable of existence within the range of temperature used in ordinary vulcanisation, naturally prompt enquiries as to a possible difference in the activity of these various modifications of the vulcanising agent. The forms most likely to be involved are (*a*) Sλ, the modification represented by ordinary crystalline sulphur, (*b*) Sμ, the insoluble modification constituting part of genuine "flowers of sulphur" and corresponding with the viscous constituent of molten sulphur, and (*c*) Sπ, a more brightly coloured and more soluble variety, present in a small proportion with much Sλ in the equilibrium mixture yielded by ordinary sulphur at temperatures a little above its melting point; the proportion of Sπ increases markedly if the temperature is raised to 140° or higher (Aten, Z. physik. Chem., 1912, 81, 257; 1913, 83, 442; 86, 1. Proc. K. Akad. Wetensch., Amsterdam, 1918, 20, 824).

Tests made with mixtures of rubber with soluble sulphur (Sλ) and insoluble sulphur (Sμ) respectively, under ordinary technical conditions, indicate that the vulcanising effect of these two varieties is practically the same (Twiss, Annual Reports of the Progress of Applied Chemistry, 1919, 4, 327); this result, however, is probably to be attributed to the rapid change of Sμ at such temperatures into the equilibrium mixture consisting mainly of Sλ with some Sπ (Beckmann and others, Z. anorg. Chem., 1918, 102, 201; 103, 189).

Between 128° and 168° C. the temperature coefficient of the chemical reaction between rubber and sulphur, *i.e.* the proportion by which the rate is increased on raising the temperature 10° C., is surprisingly constant, and in view of the alteration of the composition of the equilibrium mixture with rise of temperature, the comment has been made that this is indicative of comparable vulcanising capacity on the part of the modifications present (Twiss and Brazier, J., 1920, 125 T).

Although the difference observable between the forms of sulphur naturally existent at ordinary vulcanising temperatures is thus shown to be relatively slight, it must be remembered that under such conditions the sulphur will undergo fusion and then rapidly yield the equilibrium mixture. If the temperature could be maintained much lower, the rate of attainment of equilibrium could be reduced and the increased persistence of each form would afford greater opportunity for observing any difference in vulcanising capacity. The use of a suitable vulcanisation catalyst, *e.g.*, aldehyde-ammonia, enables experiments to be made at a sufficiently low temperature. It is a little unfortunate that the powerful organic catalysts generally should be basic substances such as also tend to catalyse the mutual inter-conversion of the sulphur allotropes, but, as is demonstrated by the results now submitted, the disturbance from this direction is not sufficient to mask completely the sought effect.

In the first set of experiments the varieties of sulphur used were (*a*) a high grade finely powdered sulphur soluble in carbon bisulphide and consisting entirely of Sλ, and (*b*) an extracted sublimed flowers of sulphur 93% insoluble in carbon bisulphide and consisting mainly of Sμ. Mixtures were made of each of these with selected pale crêpe rubber of known rate of vulcanisation; the composition in each case was rubber 90 parts, sulphur 10 parts, and aldehyde-ammonia 1 part. In order to ensure as closely comparable composition and conditions as possible, the sulphur in both cases was first mixed with an equal weight of the rubber and the composition of each stock checked before introducing the correct amount of each into the final mixtures. Similarly the aldehyde-ammonia was first mixed with 9 times its weight of the rubber so as to increase the accuracy with which equal proportions of this "stock" could be introduced into the two batches of equally "worked" rubber. Vulcanisation was effected, with the two mixtures simultaneously, at 98°, 108°, and 118° C. Figure 1 shows the rate of vulcanisation as indicated by the gradual reduction in extensibility of the two mixtures at the respective temperatures; the trans-

verse dotted lines mark the approximate position of the "optimum tensile strength" where this was observed. Figures for combined or residual free sulphur are not given because their satisfactory determination in the ordinary way is impossible in the presence of $S\mu$ (see Twiss, J., 1917, 789).

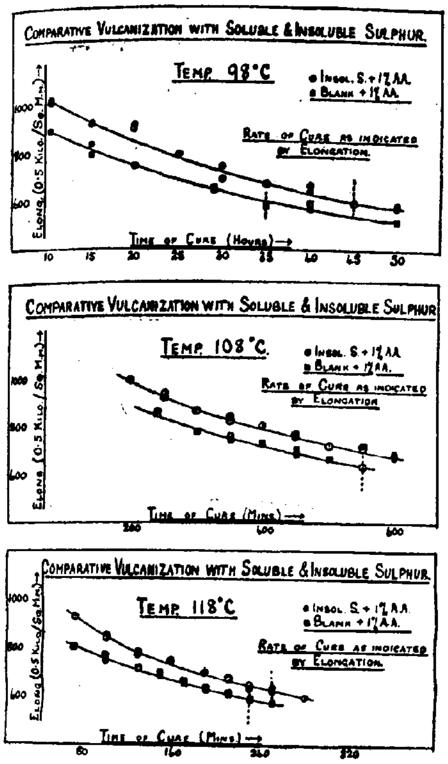

Fig. 1.

It will be noted that under the conditions of these experiments the vulcanising effect of $S\mu$, particularly at the lowest temperature, is definitely inferior to that of $S\lambda$.

Taking an extensibility of 700% as a standard for comparison, the difference in the rate of vulcanisation of the two mixtures is clearly seen from the respective periods required, and the more rapid conversion of $S\mu$ into $S\lambda$ with rise of temperature is reflected in the corresponding decrease in the temperature coefficient.*

	Rate of vulcanisation.				
	$S\mu$ (93%).		$S\lambda$.		
	Time required.	Temp. coefft.	Time required.	Temp. coefft.	Relative effect, $S\mu : S\lambda$.
98° C.	32 hours	—	23 hours	—	1 : 1·4
108°	550 mins.	3·5	440 mins.	3·1	1 : 1·3
118°.	185 mins.	3·0	140 mins.	3·1	1 : 1·3

* In these experiments vulcanisation was effected uninterruptedly for the full periods, the temperature of the oil bath being maintained constant for the whole of the time. The greater value of the temperature coefficient obtained previously with $S\lambda$ for the interval 98°-108° C. (Twiss and Brazier, *loc. cit.*) is to be ascribed to the fact that the earlier experiment at 98° C. was made in two stages, with the result that the vulcanisation would be retarded somewhat on account of the partial separation of sulphur from solution in the rubber half-way through the experiment.

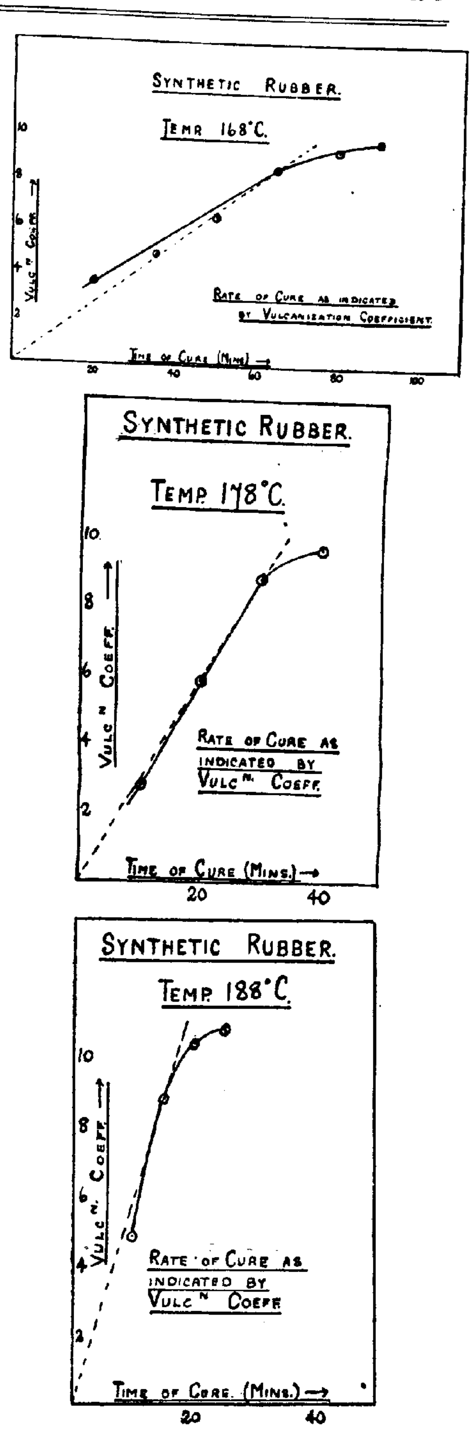

Fig. 2

An experiment with similar mixings of the same rubber and two forms of sulphur in the same proportions, but without the catalyst and at 148°, confirmed the earlier observations (Twiss, *loc. cit.*) as to the closely comparable effectiveness of the $S\mu$

and $S\lambda$ at this temperature, the relative effectiveness calculated in the same way as above being 1:1·06.

These results as a whole demonstrate that at the ordinary vulcanising temperatures, *e.g.*, 148°, $S\mu$ changes so rapidly into $S\lambda$ that no appreciable difference can be detected in the rate of vulcanisation, the effect in each case being that actually produced by $S\lambda$. At lower temperatures it is possible to detect a distinctly feebler effect in the mixture containing $S\mu$. The possibility that this difference may be characteristic not of $S\mu$ but of $S\pi$, which is formed together with $S\lambda$ from the less stable $S\mu$ at such temperatures, is hardly in accord with the almost identical effect observed at 148° C. (see above) and with the results given below. In all likelihood therefore the difference arises from the $S\mu$ itself and is probably not explained completely by the lower solubility of this form of sulphur.

From the constancy of the temperature coefficient of the reaction between ordinary sulphur and rubber at 138°—168° C., over which range $S\lambda$ gives rise to an increasing proportion of $S\pi$, it would appear that $S\pi$ and $S\lambda$ are of almost equal activity in this direction. This result is of interest in view of Aten's observation (Z. physik. Chem., 1914, **88**, 321) that $S\pi$ retards the action of $S\lambda$ on silver and mercury.

There appeared to be some hope of obtaining more evidence of the activity of $S\mu$ relative to $S\lambda$ by making vulcanisation experiments with rubber at higher temperatures, at which sulphur is known to undergo a marked change in molecular complexity probably corresponding with a rapidly increasing proportion of $S\mu$ in the equilibrium mixture (Beckmann and others, *loc. cit.* Kellas, Trans. Chem. Soc., 1918, **113**, 903. Smith, Proc. Roy. Soc. Edin., 1905, **25**, 588, 590; Smith and Carson, *ibid*, 1906, **26**, 352). Unfortunately with ordinary rubber the chemical change accompanying vulcanisation would then be too rapid for convenient examination, and recourse was therefore had to the use of synthetic rubber which, as is well known, is relatively sluggish in vulcanisation; the sample used was of "methyl-rubber," *i.e.*, polymerised dimethylbutadiene, which was free from artificial catalysts and "elasticators." On account of the hardness of the vulcanised products obtained with such synthetic rubber, no physical tests were possible and the rate of reaction was followed only by the gradual disappearance of sulphur into combination. The composition of the original mixture was sulphur ($S\lambda$) 10·4%, methyl-rubber 89·6%. Experiments were made at 168°, 178°, and 188° C., the results being as given in figure 2.

It is remarkable that the disappearance of most of the sulphur into combination appears to follow the approximately rectilinear course already observed with natural rubber (Skellon, Rubber Industry, 1914, 172; van Iterson, Comm. Netherland Gov. Inst. for Advising Rubber Trade, 1918, **7**, 247); if, as suggested by van Iterson, this is due to autocatalysis it is evident that the non-caoutchouc constituents of natural rubber are not responsible.

The results are not quite as smooth as could be desired, but if comparison is made of the time required for the attainment of the various degrees of vulcanisation at different temperatures, the temperature coefficients in each case are greater for the interval 168°—178° than for 178°—188°.

The apparent slight increase in the temperature coefficient during the progress of the reaction appears to indicate the existence of a very brief initial period of greater reactivity. This may be due to the fact that the sulphur initially is composed practically entirely of $S\lambda$, which rapidly undergoes conversion into the less active equilibrium mixture; it might, however, be caused by the presence in the synthetic rubber of a small proportion of some more active material. There is no such regular alteration observable in the figures calculated in a similar way from the experiments with ordinary rubber and sulphur at 138°—168° C. (Twiss and Brazier, *loc. cit.*).

A better comparison of the temperature coefficients is probably given by the ratio of the tangents of the angles included between the horizontal axis and the line (dotted in Fig. 2) between the origin and the point representing the end of the "rectilinear" course of the vulcanisation process. This method of comparison likewise shows a smaller increase in the rate of reaction for the second interval.

	Time (mins.).			Temp. coefft.	
Vulcan, coefft.	168°.	178°.	188°.	178°-168°.	188°-178°.
4	25	14	—	1·8	—
5	34	18	10	1·9	1·8
6	43	21	11	2·0	1·9
7	52	24	12	2·2	2·0
8	61	28	14	2·2	2·0
9	73	31	15	2·4	2·1
angle	33°	56°	71°	—	—
tan.angle	0·65	1·48	2·90	2·3	2·0

The smaller coefficient for the higher temperature interval suggests that the sulphur equilibrium mixture at the higher temperature is relatively less effective than the equilibrum mixture existent at the lower temperature; as the difference in the composition of the two equilibrium mixtures will be a smaller proportion of $S\lambda$ and a greater proportion of $S\pi$ and $S\mu$ at the higher temperature, and as the earlier considerations lead to the view that the effectiveness of $S\pi$ is very little different from that of $S\lambda$, it follows that the results again indicate a somewhat inferior vulcanising capacity for $S\mu$. It must be remembered, however, that the observed differences in such experiments, based on the relative activity of interchangeable modifications of a chemical substance, will be diminished by the tendency of the equilibrium automatically to adjust itself as the more active form disappears.

Although these results indicate a difference between the activity of $S\mu$ and of $S\lambda$ or $S\pi$, the outstanding fact is not the existence of this difference but its relatively small magnitude. The three forms are of such diverse general characteristics that much greater differences might have been expected. Under the conditions of ordinary technical practice indeed, the possibility of alteration in the relative proportions of the various modifications of sulphur is not likely to form an appreciable disturbing factor in vulcanisation, and the only instance of any special form of sulphur (as such) showing special vulcanisation features appears to be that possibly involved in the recently discovered method of treating raw rubber with sulphur dioxide and hydrogen sulphide.

For the experiments recorded above, use was made of the very convenient oil-bath method of vulcanisation.

London Section.

Meeting held at Burlington House on January 3, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE SMITH CONTINUOUS SYSTEM OF CARBONISATION.

BY GEORGE H. THURSTON, M.I.E.E., A.M.S.M.E.

The carbonisation of coal has been fully dealt with in this country but up to the present, so far as the author is aware, no complete description has been given of the system designed and perfected by Mr. Charles H. Smith, of New York, or of the plants constructed on this system and producing a smokeless fuel called "Carbocoal" at the rate of 550 tons per day. One of these plants situated at Irvington, New Jersey, has been in constant operation for the past two years.

The Smith continuous system is a combination of low- and high-temperature carbonisation, and the inventor has retained all the advantages connected with the high oil recovery in the former, and in addition has succeeded in increasing the yields of tar and sulphate of ammonia by means of the latter, at the same time producing a free-burning smokeless fuel that stands rough handling with a minimum of loss.

In order to obtain low operating costs on a carbonisation plant it is essential that the process should be continuous, and lost time reduced to a minimum. Full advantage must be taken of labour-saving machinery and manual labour eliminated as much as possible. To carry out this effectively necessitates the construction of a plant capable of dealing with at least 200,000 tons of coal per annum. The importance of these features is fully realised in the United States, and in the 150,000-ton carbocoal unit of the 1,500,000-ton plant built at Clinchfield, Va., for the International Coal Products Corporation of Virginia, to operate the Smith process, labour-saving devices are used to the utmost extent. This plant commenced producing in July, 1920, and is working smoothly.

An objection frequently raised to the fuel obtained from low-temperature carbonisation is its friability and bulk, which make its transport difficult and costly. "Carbocoal" is carried on the railways in the United States at the same rates as coal, and is not subject to these disadvantages.

In the Smith continuous system of carbonisation the coal, which is crushed to pass a $\frac{3}{8}$ in.-mesh screen, is subjected to a primary carbonisation at a temperature of about 480° C. to reduce its volatile content to a uniformly low figure, whereby it is converted into a friable residue containing 7—10% of volatile matter, called "semi-carbocoal." The period of this process is 2—3 hours, and the operation is continuous.

After passing through the retort, the material is ground and mixed with a suitable percentage of pitch and briquetted. The briquettes, which contain about 15% of volatile matter, are then heated to 1000°—1100° C., which drives off all but 3 or 4% of the volatile content and leaves them firm and hard. The quality of the briquettes is influenced by the ash content of the coal, but since this is evenly distributed throughout the mass, the clinkering of the fuel during combustion is absent except when the ash has a very low fusion point, and it has been found that, although the coal loses 2% of its calorific value by carbonisation, the actual heating efficiency of Carbocoal—referred to the coal from which it is made—is 94%.

The tar recovered from the primary retort and by scrubbing the gas contains the usual oils and ammonium sulphate found in tar recovered by the low-temperature process. The yield, owing to the low temperature employed, is high, the actual quantity recovered and its value naturally depending on the constituents of the coal. The tar recovered from the secondary carbonisation contains a large percentage of heavy oil and pitch, and when distilled considerably increases the total yield of ammonium sulphate.

The gas produced in the Smith system varies in quality and quantity; that from the primary retort has a calorific value of 650—700 B.Th.U. per cb. ft., and the quantity distilled from a 35% volatile coal is between 5600 and 6700 cb. ft. per ton. In the secondary retort the gas has a value of 350—400 B.Th.U. and the yield is about 4480 cb. ft., or an average total of 10,630 cb. ft., with a calorific value of about 548 B.Th.U. In the present stage of development, the system, after supplying all the demands, furnishes a surplus of 2240 cb. ft. of gas.

Description of plant.

By referring to Fig. 1, which illustrates a typical flow diagram of a plant laid out to produce "Carbocoal" by the Smith continuous system of carbonisation, it will be seen that the coal is delivered into the track hopper or storage bin, *a*, and transported by means of the belt conveyer, *b*, to the hopper of the coal crusher, *c*, which reduces it to about $\frac{1}{8}$ in. size; the fine coal is then raised by the elevator, *d*, and distributed by means of the conveyor belt, *e*, to the hoppers, *f*, which automatically feed the primary retorts, *g*, a detailed description of which will be given later (see also Figs. 2, 3, and 4). The black, friable, spongy mass formed in the primary retort is conveyed by means of the paddles in the retort to the discharge orifice, where it is deposited in pieces not over 6 in. in size in the water-jacketed discharge hopper, *h*, situated immediately below the retort. From this it is fed by the worm, *i*, to the conveyor, *j*, which transfers it to the storage bin, *k*.

The mass is then fed by means of a feeder conveyor, *l*, to the crusher, *m*, where it is broken up to $\frac{1}{8}$ in. or less, after which it is raised by the elevator, *n*, to the mixer, *o*, in which it is mixed with 8—10% of its weight of liquid pitch, stored in the vessel, *r*. The mixture then goes to the "fluxer," where the two materials are intimately mixed in conjunction with steam which melts the pitch, and passes from there into a briquetting press, *q*, of the roll type. The raw briquettes are then passed to the storage bin, *u*, by means of a cooling conveyor, *t*. This conveyor is of sufficient length to enable the briquettes to be completely set by the time they arrive at the storage bin, and they are thus ready for the secondary carbonisation. Underneath the briquetting press is a second conveyor, *s*, for recovering the fines made from the press and returning them to the fluxer, so that only whole briquettes are carried to the storage bin. The briquettes are taken from the storage bin by means of a lorry car, *v*, and deposited in the secondary retort, *w*, where the final carbonisation is completed.

The high-temperature retort illustrated in Fig. 5 is a modification of the inclined gas retort; the modification consists of the compartments being made rectangular in place of the usual D shape; the retort has three compartments each containing two carbonising chambers that are charged and discharged by gravity.

The temperature to which the briquettes are subjected is approximately 1090° C., which expels practically all the volatile matter. The time occupied in this operation is about six hours per charge. The briquettes are then discharged by gravity into the

car, *x*, transferred to the loading station by means of the track, *y*, and quenched with water, and are then ready for despatch.

The Smith retort.

The retort invented by Mr. C. H. Smith constitutes the most important link in the carbonisation system developed by him. The retort, which is cylindrical and about 18 ft. long, has an inverted heart shape (see Fig. 2). It is constituted of individual blocks of carborundum containing a special asbestos-packed tongue-and-groove expansion joint. Carborundum was selected after long and extended trials, in which retorts constructed of other refractory material and metal were used. When its heat-conducting and wearing qualities are taken into consideration it is considered to be the best material for the purpose that has been discovered up to the present. The end walls of the retort are of cast iron lined with firebricks and contain the necessary openings for the feed and the paddle shafts, which are parallel with the axis of the retort. The shafts pass through asbestos-packed stuffing-boxes, forming part of the cast-iron covers on the end walls, and are carried by substantial sleeve bearings. The paddles for stirring the material and moving it through the retort have a radius of 2 ft. 3 in., and the clearance between the end of the paddles and the carborundum muffle blocks is ⅜ in. The paddles, which are bolted to the 12-in. shaft, are mounted alternately, so that each paddle wipes the opposite shaft, and its face is inclined sufficiently to push the material through the retort. The shaft makes one revolution in eight minutes, and the power required is 2 B.H.P. It has been found in practice that the speed can be considerably accelerated if it is considered desirable to stir up the coal to a greater extent. Under average operating conditions it is the practice to keep the retort about half full, which provides ample room for intumescence of the coal without interfering with its operation.

The feeding is accomplished by means of a single screw conveyor running in a closed pipe; the packing of the material is depended on for the necessary gas seal. The conveyor is driven by a motor, and the average power taken is about 5 B.H.P. The regulation of the feed is effected by starting and stopping the motor by means of contacts mounted on the paddle shaft gear wheel.

The apparatus for discharging the material is situated at the bottom of the retort, and consists of arms mounted on a revolving shaft, which serves to break up the product as received from the retort and deliver it in a suitable condition to a screw conveyor operating in a water-cooled pipe turned up at the end to form a gas seal.

Stripped gas is used for heating; the burners are placed in the flues of the brick setting surrounding the retort, which also contains the usual recuperative features for pre-heating the air by means of the heat in the waste gases. Sufficient heat is maintained in the retort so that the outgoing carbonised product has a temperature of about 480° C. When treating American coal containing 35% of volatile matter and 0·72% of moisture the retort has a capacity of one ton per hour.

Products of distillation.

The products of distillation pass out at the top of the retort and are not subjected to any increase in temperature, so that the tar obtained possesses all the characteristics of a low-temperature tar, and the yield is exceptionally good, as will be seen from the following results obtained from a ton of typical high volatile Pittsburgh coal:—

Briquettes.	Primary furnace.	Secondary furnace.	Total 70% dry.

FIG. 3.

The 28 gallons of tar when distilled gives a yield of 18·6 gallons of distillate, the remainder being pitch, which is used in making the briquettes.

If, on investigation, it is found profitable to "crack" the tar into motor spirit, naphtha, tar acid, and fuel oils, this can be accomplished by the installation of the usual by-product plant. It is estimated that all the necessary heat and power required for the by-product plant will be furnished by the 2240 cb. ft. of surplus gas obtained from the carbonising process. The by-product plant is well known, and as it does not form an integral part of the plant it is not the intention to devote any further space to its description.

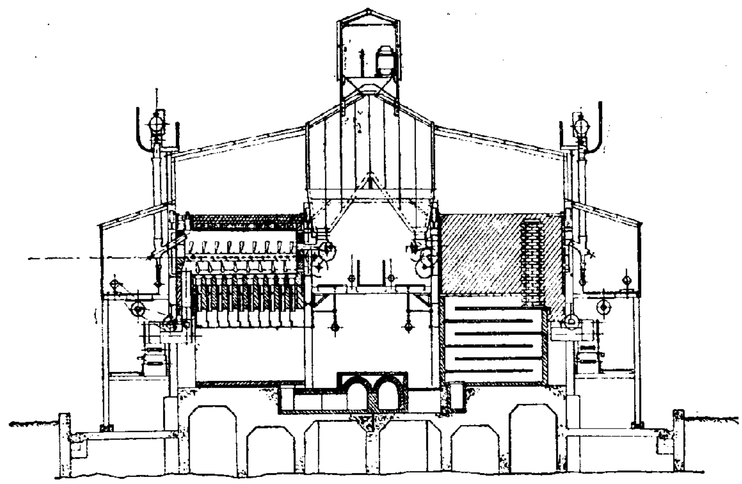
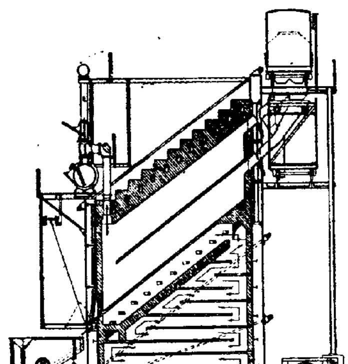
Pre-heating.

That the Smith retort is capable of dealing successfully with a great variety of fuels can be seen by referring to Table I., and there is no apparent reason why British fuel should present any greater difficulties than those already treated in the retort. It is obvious that the results obtained from the different kinds of fuel will vary, and that careful investigation is necessary before laying out a plant.



Primary retorts—general cross-section.

FIG. 4.



Secondary retort—cross-section.

FIG. 5.

The investigation may point to the necessity of washing the coal, with the possibility of having to subject it to preliminary drying for the purpose of driving off the moisture before being fed into the primary retort. To accomplish this a simple form of dryer has been designed by Mr. Smith. In this device the waste gases from the retort are passed through it on the way to the chimney. By means of this the moist coal is heated to 150° C., and the period of distillation in the primary retort is reduced proportionately. In addition a considerable amount of moisture is eliminated from the gas by this pre-heating, and, as this does not have to be removed from the tar, the work performed in the more expensive unit is reduced to a minimum.

Use of Carbocoal in boilers, furnaces, and blast-furnaces.

Judging from the published reports of tests made by the United States Navy Department, carbocoal, when burnt in the furnace of a Babcock and Wilcox boiler, compared favourably with the coal from which it was made. The tests indicated that one pound of Carbocoal evaporated 9·09 lb. of water from and at 212° F., as against 9·59 lb. of water for the coal it was derived from. Similar tests were also made on a horizontal tubular boiler at the Fosdick Machine Tool Company's works. The fuels used were bituminous slack, having a calorific value (dry) of 14,120 B.Th.U., as against 12,470 B.Th.U. for carbocoal. The relative evaporation was 6·59 lb. and 7·34 lb. of water per hour from and at 212° F.

Carbocoal has also been tried with success in a locomotive. One very valuable feature of the briquettes is their great strength, which has been obtained without sacrificing their porosity. This feature enables the fuel to be roughly handled and transported long distances with a minimum of loss due to breakage. Recent tests have demonstrated that it has all the advantages of coal as a powdered fuel and at the same time is immune from spontaneous combustion. This, in addition to its occupying very little more space than an equal weight of coal, makes it an excellent bunker fuel for marine work. The hardness of carbocoal and its great strength when subjected to heavy pressure make it suitable for use in the blast furnace; this is of considerable importance, as it indicates that a fuel suitable for metallurgical purposes can be produced by means of the Smith system from coal which the coke oven is incapable of dealing with.

Tests to ascertain the crushing strength of carbocoal made by Messrs. Kalmus, Comstock and Wescott, Inc., Industrial Research Engineers, of Boston, U.S.A., in conjunction with Dr. Walter Runge, of the International Coal Products Corporation, indicate that the average crushing strength was 943 lb. per square inch at a temperature of 1400° C.; the crushing strength of coke at room temperature was 944 lb. per square inch. The apparent specific gravity of both carbocoal and coke was found to be 0·973 at room temperature.

Discussion.

Dr. W. R. Ormandy said that the plant described appeared to him to resemble the Del Monte retort with two stirrers instead of one, whilst the soft coke was made into high-temperature coke. As far as he could gather, in this process the gases given off by low-temperature distillation were added to those given off by high-temperature distillation, and a large amount of pitch was added to the coke. With the Del Monte process, in which a continuously moving worm was working in a sticky mass of good Durham gas coal, there would result a soft, friable coke, which would be very porous. If that coke were mixed with pitch and heated to 1090° C., there was strong presumptive evidence that a hard coke would result, which would probably stand the pressure of the blast furnace. The description of the Smith process led him to think that an effort was being made to claim the advantages both of low- and high-temperature distillation. If the process gave a hard coke this would not have the advantages which were attached to low-temperature coke, which would ignite readily and was an admirable fuel for ordinary household use. The harder coke might be better for metallurgical purposes, and would probably be very suitable for steam raising, and it would certainly be better for transport purposes. On the whole, however, it did not seem to him that there was a great deal of novelty in this beyond the attempt which had been forecasted by many writers, to get over the difficulty of the soft, fine coke produced by a really low-temperature process by briquetting it, and then re-heating the briquettes in this semi-continuous process. It was interesting to find that, although the primary process was to be carried out at a temperature not exceeding 480° C., the inventor did not seem to have found that an iron retort was satisfactory, and had resorted to the use of carborundum. That material had been used years ago by Dressler for making the combustion tube of his continuous ceramic furnace; in this, however, it was used, with a similar sort of expansion joint, at a temperature of 1500°—1700° C., where a metallic material could not be used. He failed to see what advantage there was in the use of a carborundum tube in the place of an iron tube in the present system. It seemed to him also that the Del Monte system of taking the gas off from a number of points from the top of the retort was an advantage compared with using the carborundum retort with the gas exhaust at one end, so that the products of distillation were exposed for a much longer time to the temperature of the inside of the hot retort.

Dr. R. Lessing said that the process appeared to be working on a fairly extensive scale. He believed the American Government had given a grant in connexion with the plant. He agreed with Dr. Ormandy that there might be features of the process which could not be claimed to be novel, but to-day that was really not the question in low-temperature carbonisation. It was rather a question of applying well-known principles in a workmanlike fashion, and, what was more important, in a manner which was based on scientific investigations, because what was missing to-day was the scientific data on which plants could be constructed. Until these data were obtained in a great mass for any number of coals, and, what was equally important, he ventured to think, in connexion with the materials of which retorts had to be made, the progress which was desired would not be made. We knew next to nothing to-day of the conductivity of coals under the conditions under which large masses had to be carbonised, and it was this question of conductivity that was responsible for all the failures that had been experienced hitherto. They had to deal with a problem in which a great deal of heat had to be forced into a material which was less conducting than the coke or semi-coke obtained at high temperature, and this had to be done from a lower starting point in order not to decompose the material at the walls of the retort to the same extent as at high temperature. They had to deal, therefore, with a very much less steep heating gradient, and that was the crux of the failures hitherto experienced. Until these matters had been thoroughly thrashed out in a scientific manner there was very little hope of getting this problem really solved. On the other hand, there was not the slightest doubt that the problem was one worthy of solution, and any money spent in this direction, provided it was done on really scientific lines, ought to produce results of great economic value.

Mr. E. Lawson Lomax, referring to the quality of the oils produced by low-temperature carbonisation processes, said that all the advocates of these processes claimed to get so many gallons of oil per ton of coal carbonised. They did not, however, say what kind of oil it was nor whether it was free from water when measured. From his experience in handling these oils he had found that most of them were very difficult to refine, and also it was very difficult to get accurate readings of the quantities, owing to the fact that so much water was held in suspension. At the present time, and having regard to our present knowledge of the chemistry of these oils, they could not be classed as having any value except for fuel purposes, and therefore in most cases the values assigned to them by the advocates of the various processes were fictitious. The figure of 20 to 30 cents per gallon mentioned in connexion with the Smith process was a very high one for fuel oil to-day. A large amount of research work would have to be carried out on these oils before they could be refined profitably, and that work should be done before the processes were brought on the market.

Mr. E. B. Edwards, replying on behalf of the author, said that one of the differences between the Smith retort and the Del Monte retort was that the latter would not handle a swelling coal, whereas the Smith retort would handle coking or non-coking coals. The use of the carborundum linings was found necessary, owing to the high temperature in the heating flues; metal linings for the retorts would not withstand the temperature. By this process it was possible, by stirring the coal in the retort, to have a very high temperature in the flue and at the same time to have a low temperature in the retort itself. This gave a high capacity to the retort, which worked at the rate of 1 ton per hour continuously day in and day out. Another reason for the use of carborundum was its high conductivity. In reply to a statement by Dr. Ormandy, Mr. Edwards said that the fuel was now being used and sold in large quantities for the same purposes for which anthracite was used and had also been used in open grates and anthracite stoves in England. It was only after long scientific investigations and research work at the plant at Irvington, and based on its results, that the commercial plant at Clinchfield was erected. The trouble with low-temperature processes in England at the present time was that the processes were non-continuous, with the result that it was necessary to have low temperature in the flues, and it took about twelve hours to carbonise a charge of coal. The material must be agitated in order to release the gases and reduce the time of carbonisation; in America they were using a continuous retort in which the material was agitated by means of the paddles on the shaft. With regard to the question of the oils and their disposal, it was found in America that after distilling the tars, there was no difficulty in disposing of the oils. They had been able to get toluol and benzol by a very simple cracking process; in fact, the United States Government looked into the process during the war and gave a

grant for the purpose of installing a cracking plant. It was proved that toluol and benzol could be manufactured to meet with the Government requirements for making TNT and picric acid.

Meeting held at Sydney on November 10, 1920.

MR. R. W. CHALLINOR IN THE CHAIR.

THE INFLUENCE OF SODIUM CHLORIDE AND SODIUM SULPHATE ON THE SOLUBILITY IN WATER OF SODIUM β-NAPHTHALENESULPHONATE.

BY W. TERNENT COOKE.

The two systems water—sodium β-naphthalenesulphonate—sodium chloride or sodium sulphate have been investigated over the temperature range 25°—65° C. at atmospheric pressure.

The sulphonate was made by heating together 1 g.-mol. of powdered naphthalene with slightly more than 1 g.-mol. of sulphuric acid (93% H_2SO_4) to 180° C. for 3—4 hours. After cooling, and diluting to about 1 litre, 2 g.-mols. of common salt was added dissolved in about 1 litre of water. The precipitated sulphonate was fractionally crystallised until free from sulphate and chloride. It did not melt below 275° C. and was quite neutral to litmus. The sodium sulphate was used in the anhydrous form; the sodium chloride was Kahlbaum's purest fused salt.

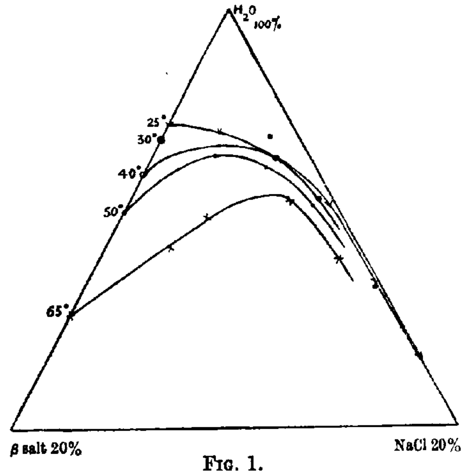

FIG. 1.

The two thermometers used were found not to differ by more than 0·1° from standards in the laboratory. Up to 50° C. the temperature was kept within 0·1°, and at 65° to within 0·2°.

Weighed quantities (0·2—5 g.) of sulphonate and of either sulphate or chloride were mixed with 10 c.c. of water in small glass vessels which were immersed in a thermostat and agitated for about 24 hours. Samples of the liquid were then withdrawn through a small filtering plug of cotton wool into a pipette jacketed with hot water, and the weights of the solution and of the salts left on evaporation were ascertained. The salts were dried at a temperature up to 150° C., trials having shown that the sulphonate is unaffected at this temperature. The dried salts were quantitatively analysed for sulphate and chloride, respectively, by precipitation as barium sulphate, or by titration with standardised silver nitrate solution, using chromate as indicator. Trials with known amounts showed that both these methods are accurate when sodium chloride, or sulphate, is mixed with an equal weight of sulphonate. Incidentally, the solubility of the sulphonate alone had to be determined as only one value, that at 23·9° C., could be found (Thorpe, Dict. Appl. Chem., 1912, III., 574). The solubilities of the sulphate and chloride were taken from Landolt and Börnstein's tables.

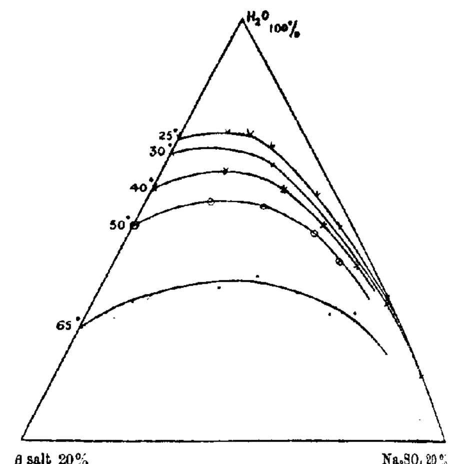

FIG. 2.

In one experiment a mixture of 1·5 g. of β salt, 0·3 g. of sodium chloride, and 10 c.c. of water was shaken together for 24 hours at 65° C.; 5·2668 g. of solution was filtered off, and this weight of liquid left 0·6003 g. of mixed salts on evaporation. These salts required silver nitrate solution equivalent to 0·1544 g. of NaCl. Therefore 0·4459 g. of β salt was present. The solution contained therefore:—Water 4·6665 g. (88·57%), β salt 0·4459 g. (8·47%), sodium chloride 0·1544 g. (2·93%). The results obtained are shown in the accompanying diagrams.

The curves show that the solubility of the β salt is reduced practically to zero when the concentration of the inorganic salt reaches about 10 g. in 100 g. of solution, especially at lower temperatures. The figures are derived from experiments made by using the β salt in excess and gradually increasing the amount of inorganic salt. Applying the ordinary method of graphical analysis to this three-component system, and from the appearance of the insoluble residues, the residue in each case is found to be the organic salt. The curves, therefore, represent the solubilities of the organic salt in solutions of the inorganic salts. An attempt was made, at 25°, to find the point of intersection of the curve shown in the figure with the curve representing the solubility of sodium sulphate in presence of the β salt. Two experiments were made at 25° using excess of both salts. The evaporated filtrates left 1·1444 and 1·302 g. of residue respectively, which residues yielded barium sulphate equivalent to 1·1284 and 1·2835 g. of Na_2SO_4 respectively, showing that the influence of the β salt on the solubility of the sulphate is practically negligible. The point of intersection lies, therefore, practically on the solubility curve of the sulphate.

The above work was carried out in the Chemical Department of the University of Queensland, and I desire to thank the authorities of that University, and especially Prof. B. D. Steele, for granting me every facility for work. I am also indebted to Prof. Steele for the interest he took in the research.

The University, Adelaide.

Communications.

THE ESTIMATION OF COCONUT AND PALM-KERNEL OILS IN FAT MIXTURES IN WHICH BOTH OILS MAY BE PRESENT.

BY W. N. STOKOE, B.SC., A.I.C.

It is common knowledge that the estimation of coconut and palm-kernel oils in mixtures when both are present is a matter of great difficulty owing to the similarity in composition of the two oils. Coconut oil, however, is richer than palm-kernel oil in the lower fatty acids, as is indicated by its higher Polenske value. Further, the insoluble fatty acids from coconut oil which distil over in the Polenske test are liquid at room temperature, whereas the volatile acids obtained from palm-kernel oil under the same conditions are solid. This difference suggested a possible method for the identification and estimation of the respective oils.

Several methods for the estimation of coconut and palm-kernel oils in mixtures have been described in the literature. Burnett and Revis (Analyst, 1913, 38, 255) have devised a method which depends on the relative solubility of the barium salts of the insoluble volatile acids in alcohol of definite strength. The temperature of turbidity on cooling is observed, palm-kernel oil giving a higher figure than coconut oil. Mixtures of the two oils are stated to give "turbidity temperatures" proportionately intermediate between the extreme values given by the pure oils. This method is expensive owing to the quantity of strong alcohol required, and has the disadvantage that the solution of the barium salts in alcohol is seldom perfectly clear, and the exact "turbidity point" is often difficult to judge accurately. A second method devised by Blichfeldt (J., 1919, 151 T) depending on the m.p. of the insoluble volatile acids has been published; in the preliminary work preceding this investigation a modification of this method was tried, but without success. After further experiment the following method was devised.

In the standard Reichert-Polenske process, after distilling 110 c.c. the liquid is cooled and the insoluble acids collected on a filter; the condenser tube is rinsed down with 20 c.c. of warm water (30°—40° C.), which is poured over the filter. The filter paper is washed with warm water (30°—40° C), and as soon as the last drop of water has drained through several capillary tubes (internal diameter of 1 mm.) are filled to the depth of ½ in. with the now melted acids. Two of the tubes are immediately attached, one on either side, by means of a small rubber band, to a thermometer graduated to read 1/10°, and the thermometer fitted into a test tube by means of a cork having a hole through which the thermometer is placed. The tube is supported in a beaker containing ether, the surface of which should be above the level of the acids in the capillary tubes. A rough idea as to whether the bulk of the acids is from palm-kernel or coconut will have been obtained from the appearance of the acids in the original Reichert-Polenske distillate. If the acids are solid at ordinary temperature it is necessary to warm the ether to about 30° C. A gentle stream of air is forced through the ether by means of a foot bellows so as to lower its temperature gradually, the rate of cooling being so adjusted that the temperature of the ether is 2° C. below that registered by the capillary tube thermometer. As the cooling progresses the fatty acids will become slightly cloudy, then a distinct "seeding" or crystallising will occur. At the first appearance of crystals the temperature is noted. This "seeding point" is quite definite and sharp. At this point the acids in the capillary tubes appear liquid with a number of tiny white crystals along the sides of the tube. It is important in performing the test that the rate of cooling should be regular.

The following tables show results obtained by this method. As was to be expected, there is a slight variation between the figures obtained for samples of different origin. The oils used in the mixtures were made by mixing equal quantities of the different individual samples in order to obtain an average result:—

Mixtures containing only coconut and palm-kernel oils.

Coconut.	Palm-kernel.	"Seeding" point, ° C.	Average.
%	%		
85	15	11·8 11·6 11·6 11·9 11·6 12·0 12·0	11·8°
75	25	13·5 13·4 13·2 13·2 13·2 13·5 13·2 13·0	13·4°
60	40	15·7 15·3 15·6 15·6 15·4 15·3 15·3 15·6	15·5°
50	50	16·9 17·0 16·8 17·0	16·9°
40	60	17·9 17·9 17·9 18·0	17·9°
25	75	19·6 19·4 19·4 19·5	19·5°
10	90	21·6 22·0 21·7 22·0	21·8°

Four samples of coconut oil of different origin and the same number of palm-kernel oil were examined. The highest figure for the "seeding point" of coconut oil acids was 11·4° C. and the lowest 9·9°; average 10·75. The figures for palm-kernel acids were: highest, 23·2°; lowest, 22·05°; average, 22·75° C.

Mixed fats containing 30% oleo, 10% cottonseed oil, 60% coconut or palm-kernel oil or mixtures of them.

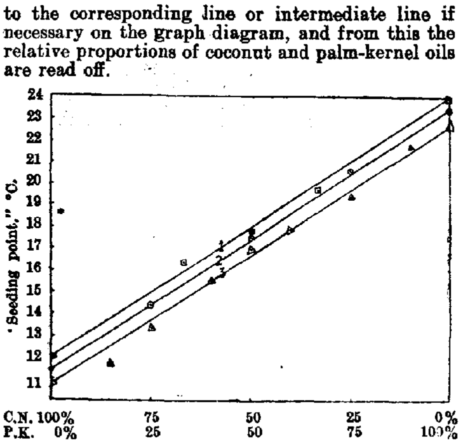
Relative proportions of coconut and palm-kernel oils.	"Seeding" point, ° C.	Mean.
Coconut 100%	11·3 11·6 11·3 11·3 11·5 11·4	11·4°
Palm-kernel 100%	23·5 23·7 23·5 23·7	23·6°
Coconut 75%, palm-kernel 25%	14·5 14·0 14·5 14·1	14·3°
Coconut 50%, palm-kernel 50%	17·6 17·6 17·5 17·5	17·55°
Coconut 25%, palm-kernel 75%	20·4 20·9 20·6 20·4 21·0 20·3	20·6°

Mixed fats containing 50% oleo, 20% cottonseed oil, 30% coconut or palm-kernel oil or mixtures of them.

Relative proportions of coconut and palm-kernel oils.	"Seeding" point, ° C.	Mean.
Coconut 100%	12·0 12·0 12·0 11·9 12·0 12·0	12·0°
Palm-kernel 100%	24·0 24·0 24·0 24·1	24·0°
Coconut 33⅓%, palm-kernel 66⅔%	20·0 19·6 19·9 19·8 20·1 19·5 19·8 19·7	19·8°
Coconut 50%, palm-kernel 50%	17·8 17·2 17·8 17·7 18·2 17·3 17·6 17·8	17·7°
Coconut 66⅔%, palm-kernel 33⅓%	16·6 16·2 16·2 16·4 16·2 16·4	16·3°

It will be observed that the presence of other fats raises the "seeding point," but that, roughly speaking, parallel lines are given on the graph. Thus in the analysis of an unknown fat mixture it will be necessary first to ascertain the approximate quantity of the coconut group of fats present by determining the saponification value and the Reichert-Polenske value. Reference is then made

to the corresponding line or intermediate line if necessary on the graph diagram, and from this the relative proportions of coconut and palm-kernel oils are read off.



Composition of coconut-palm kernel mixture.
1. 30% C.N. and P.K. in mixture.
2. 60% C.N. and P.K. in mixture.
3. 100% C.N. and P.K.

The method can be readily carried out as an extension of the standard Reichert-Polenske method, the contents of the capillary tubes being added to the alcoholic solution of the remainder of the insoluble acids and the whole being titrated as usual to obtain the Polenske value.

The following table shows results obtained on margarine samples of known composition:—

Relative proportion of C.N. & P.K. in sample.	Sapon. value.	Reichert-Meissl.	Polenske.	"Seeding" point. °C.	Relative proportion of C.N. & P.K. indicated.
Palm-kernel 100%	228·7	4·05	6·1	23·5	100% P.K.
Palm-kernel 100%	208·2	1·36	1·3	24·0	100% P.K.
Coconut 100%	223·7	5·01	6·40	11·8	100% C.N.
Coconut 100%	246·3	7·15	13·0	11·5	100% C.N.
Coconut 50%, palm-kernel 50%	244·1	5·61	11·2	16·9	51% C.N., 49% P.K.
Coconut 25%, palm-kernel 75%	228·1	4·35	7·30	20·6	26% C.N., 74% P.K.

HYDROGENATION IN THE NAPHTHALENE SERIES.

BY F. M. ROWE.

A communication on dihydronaphthalene by Straus and Lemmel (Ber., 1921, 54, 25) has drawn my attention to an error inadvertently introduced into my paper on this subject (J., 1920, 241 T) when it was written from the laboratory note-books. It is stated that both 1.4- and 1.2-dihydronaphthalenes were purified by means of their mercuric acetate compounds, whereas actually it was only the former of these compounds that was purified in this manner. My assistant, Miss Levin, attempted to purify 1.2-dihydronaphthalene by this means, but found that the mercury compound formed, of high melting point and insoluble in boiling benzene, did not yield the hydrocarbon when treated with acid, although this compound was not examined further at the time. Straus and Lemmel have now found that mercuric acetate exerts an oxidising action on 1.2-dihydronaphthalene, forming 1.2-dihydroxytetrahydronaphthalene, and that the insoluble mercury compound is $Hg.O.CO.CH_3$.

The only satisfactory method by which the purity of 1.2-dihydronaphthalene may be ensured consists in its conversion into the dibromide, which is purified by recrystallisation, followed by the removal of the bromine atoms.

THE VULCANISATION OF RUBBER.

In a letter dated January 22 to the Editor (see also India-Rubber J., 1021, 61, 177), M. A. Dubosc claims that he had already anticipated Peachey's discovery of the possibility of vulcanising rubber by the action of sulphur dioxide and hydrogen sulphide at the ordinary temperature (see Peachey and Skipsey, J., 1921, 5 T). In 1915 (*cf.* India-Rubber J., May 1, 1915) M. Dubosc had suggested that, of the various allotropic modifications of sulphur, only the colloidal form is able to vulcanise rubber. Chemically pure rubber is known to undergo vulcanisation only with great difficulty, the presence of the natural resinous and protein impurities being essential to the change, which is also aided by the addition of metallic oxides such as magnesium oxide or litharge. M. Dubosc's view of the vulcanisation process was that the resinous matter first reacts with part of the ordinary sulphur present, with formation of hydrogen sulphide, whilst any oxidised rubber or metallic oxide in a similar manner gives rise to sulphur dioxide; these gases, in solution in the rubber, then react with formation of water and sulphur, the latter being produced in the active "monatomic or colloidal" condition capable of effecting vulcanisation.

Mr. Peachey (India-Rubber J., 1921, 61, 163) replies that the new process is one of "cold vulcanisation" operating at the ordinary temperature, whereas the above theory referred to the ordinary process of hot vulcanisation; in a critical review of M. Dubosc's claim, he questions the accuracy of certain of the assumptions and directs attention to the facts that not only would any sulphur present during hot vulcanisation be in the molten condition, but that for the production of a pure ebonite containing 32% of combined sulphur, the volume of sulphur dioxide and hydrogen sulphide necessary according to above theory would be approximately 100 and 200 times respectively that of the rubber.

THE EROSION OF BRONZE PROPELLERS.

(See J., 1921, 38—45 T.)

Colonel N. BELAIEW wrote that he had been particularly struck by the similarity between the erosion of propellers and the erosion of guns. In both cases the process of erosion seemed to be divided into two phases—the preliminary, and the final. In the case of a propeller, this preliminary phase, according to Dr. Silberrad, consisted in the "water-hammer" action of water broken by vacuum bubbles; in the case of a gun, according to Tschernoff (Proc. Int. Assoc. Testing Materials, 1912, 2, A, 121), it consisted in the thermal action of the gases on a thin film of the metal on the internal surface of the gun-tube. The next stage, or the actual erosion, in both cases was due to mechanical causes only, being caused either by frictional rub of the water (on the propeller), or by the frictional rub of the particles of the gases (as in guns) forcing their way out of the tube. He (Colonel Belaiew) felt inclined, therefore, to endorse the author's view that after the surface of the propeller had been damaged by any of these agencies, further erosion was chiefly caused by the frictional rub of the water. He also thought that, just as in guns, the influence of structure was considerable, and that whilst, according to the Committee report, there might be no "connexion between the structure of a metal and the distribution of erosion," the wearing away of the metal was largely determined by the structure of the metal. The problem of structure was more complex in guns, where the gases had a certain hardening effect, and where the initial structure might therefore be altered considerably; in propellers the position was more simple, and only resolved itself into the question, as the author rightly pointed out, of finding an alloy with the most suitable initial structure.

THE PHOSPHATES OF NAURU AND OCEAN ISLANDS.

BY THOMAS STEEL.

The only detailed analyses of different types of the phosphates from these islands with which the author is acquainted have been published by C. Anderson (Records Australian Museum, Sydney, 1903, 5, 13), who gives descriptions of ten specimens, mostly from Ocean Island, with analyses of four. Anderson's descriptions and analyses agree well with some of those detailed in this paper. F. R. C. Reed (Geol. Mag., 1903, **10**, 298) describes the physical appearance of a series of specimens from Ocean Island, which agree precisely with several of the author's samples, and gives an analysis by Voelcker of a specimen described as "hard rock," which shows 4·5% of magnesia. As will be seen from the descriptions following, there is a considerable variety of types. For the specimens, which were selected with the special view of being representative, the author is indebted to his brother, Mr. F. W. Steel, who was resident on Nauru for some time. Most of the samples are from Nauru, but the Ocean Island phosphates are of precisely similar character.

Description of specimens.

1. A beautiful, compact, pale grey rock of uniform very fine texture, closely resembling the porcelain of which Wedgewood mortars are made. Fracture conchoidal, not stratified.

2. Extremely porous, sintery mass in which coral structure is well preserved, the vertical ribs in the the coral tubes being clearly defined. Bears a strong resemblance to a mass of calcified sponge.

3. Somewhat porous, in shape like coarse branching coral, but no organic structure could be detected. Some specimens are hollow, the interior being thickly lined with interlacing vermiform processes, whilst others are solid, being filled with a mixture of similar processes and of oolitic grains.

4. A breccia, consisting of small oolitic grains and rough angular fragments loosely cemented.

5. Similar to 1, but in fine layers of dark and light grey.

6. Coarse and fine loose water-worn grains and pebbles. May be described as a mixture of pisolitic and oolitic grains; grey.

7. Similar to 6, but the grains are black, being coated with a skin of humus easily rubbed off. This constitutes the surface "soil," 4 to 6 inches in depth. Ocean Island.

8. Compact, surface smooth, somewhat resembling grey flint.

9. Thin, brown layers like banded agate, dark and light brown. Very hard and dense. Breaks with a splintery fracture.

10. This sample bears a striking resemblance to a mass of commercial gum benzoin. Brown, with angular white enclosures.

11. Black, compact trachyte-like, of oolitic structure. Bears a strong superficial resemblance to a piece of dolerite. Weathers white on outer surface.

12. A hard, grey, massive rock, having numerous vesicles lined with brown material, like 10, and small spheres of same substance.

13. Resembles coarse, grey sandstone, composed of oolitic grains loosely cemented.

14. Like dense limestone, with numerous large white shell casts.

15. Fine columnar structure of coral, adherent to dense limestone. Columns about $\frac{1}{4}$ inch in diameter, with vertical radial septa dividing the tube into a series of sectors. Coral part only taken for analysis.

16. Buff and white diffusely banded, compact rock, dense and hard. From reef. Ocean Island.

17. Small sample, showing in vertical section flattened double coral tubes, each element of the double tube being about $\frac{1}{16}$ inch in diameter. The septa of the tubes are very prominent and well preserved, forming a series of superimposed closed cells, in depth about equal to their diameter. Not analysed, but high in phosphoric acid.

Unless otherwise stated, all the samples are from Nauru Island.

Only traces of iron or alumina were present in any of the samples. Varying small amounts of fluorine occur in many of the samples.

The original source of the phosphoric acid is generally conceded to have been the accumulations of guano from the colonies of sea-birds using the islands as nesting places.

Most of the samples bear evidence of having undergone considerable metamorphosis and of having been deposited either from solution or as sediment. Only two samples, 2 and 17, of those high in phosphoric acid, retain any organic structure. Of the others, 14 and 15 exhibit the remains of shells and coral respectively, but these are dolomites containing only a small proportion of phosphoric acid.

The four samples analysed by Anderson are high in phosphoric acid, and of these two are described as displaying organic structure, coral, or shell.

It is not possible to offer any opinion as to the extent to which coral has entered in the course of formation of the various types described above, but it is possible that the deposits devoid of organic structure may have been formed direct from guano without the intervention of coral. When dead coral

is submerged in sea water it becomes dolomitised by reaction between the calcium carbonate of the coral and magnesium chloride of the water, producing such samples as 14 and 15. Where the supporting rock consisted of such dolomite, the phosphatic basis of the guano, after the loss of the organic constituents by decay and leaching, may have undergone transformation by solution and redistribution without in any way affecting the inert underlying rock. Doubtless carbon dioxide in percolating rain water would materially assist in the transformation of the phosphate.

Fresh coral has been reported to contain from 0·28 to 0·84% of calcium phosphate. Fresh coral is stated (Watts' Dict. Chem., II., p. 84) to contain about 1% of magnesia and 2·1—9·4% of organic matter, the remainder being calcium carbonate.

The analysis of the above phosphates show that part only of the phosphoric acid is present as calcium phosphate ($Ca_3P_2O_8$), the relative proportions of constituents indicating the presence of a varying proportion of tetracalcium phosphate ($Ca_4P_2O_9$). The author has observed this in other natural phosphates, and, quite recently, in the deposit of "tartar" from the teeth of man, sheep, ox, and other animals (Steel, Proc. Linnean Soc. N.S. Wales, 1920, 324).

The question of origin was the subject of an important lawsuit in Melbourne some years ago. A firm of chemical manufacturers claimed that a cargo of phosphate from Ocean Island should be classed as guano owing to its reputed bird origin. Guano was admitted free of wharfage, whereas a charge of one shilling per ton was levied by the Harbour Trust on minerals, under which category they placed the "rock phosphate" of Ocean Island. The verdict of the court was in favour of the Harbour Trust.

Mr. F. W. Steel has furnished the following notes from his observations when resident on Nauru:—

"The substructure of both islands is hard dolomite without trace of coralline structure, containing embedded fossil shells. The coral pinnacles among which the phosphate deposit is found come up to the present surface and in a number of places project beyond to a considerable height, notably two large masses in the centre of Nauru, which attain a height of about 100 ft. above ground level. The highest point of the island of Nauru is stated to be about 250 ft. above sea-level. On Nauru are a number of caves in the dolomite rock; these are evidently shrinkage cracks and show but slight stalagmitic structure. In places the surface layer of the dolomite seems to have been partly phosphatised, but this may be merely a layer of phosphate deposited thereon from solution.

Around Ocean Island is a raised beach or rough flat of very limited extent, where in places are numerous pinnacle masses of coral, evidently the remains of the coral structure, and which are very rough and sharp through weathering. The pinnacles embedded in the phosphate, on the other hand, show smooth surfaces with layers of phosphatised coral. It is extremely probable that the shore pinnacles were originally surrounded by phosphate which has been subsequently washed out by the sea, as on the flat reef on Ocean Island there are numerous 'pipes' of phosphate of pisolitic structure projecting from the surface, the grains being cemented together with phosphate. These, being formed by the filling in of 'blowholes' in the coral and being harder than the latter, have remained when the surrounding coral was removed by wave action. The "pipes" stand up to as much as three feet above the reef level. The flat reef is submerged at each high tide. The sand of the beaches is all coral *débris*, shells, etc."

Meeting held at Queen's Hotel, Leeds, on January 17, 1921.

DR. L. L. LLOYD IN THE CHAIR.

THE PRESENCE OF NITRATES IN THE LEAVES OF TREES GROWING NEAR PICRIC ACID WORKS.

BY B. A. BURRELL, F.I.C., AND G. W. DOUGLAS.

In the production of picric acid by the nitration of phenolsulphonic acid large quantities of oxides of nitrogen are evolved. During the war considerable volumes of these gases sometimes escaped from the nitrating sheds to the detriment of any vegetation that might be in the vicinity.

In 1916 one of us was consulted in respect to such damage, and during that and subsequent years we examined numerous samples of leaves taken from trees growing near to a large picric acid works.

When the wind was blowing from the works to the agricultural land (about ½ a mile distant) on which the damage had and was taking place, the distinctive smell of the nitric fumes was easily perceptible.

The district was well wooded and the damaged trees could be easily recognised, the leaves being dry, shrivelled, and falling readily. When the trees were in clumps, those nearest to the works showed the most damage, those behind being to a certain extent protected. Where the trees were growing behind a wall situated between them and the works, the portion immediately behind the wall did not show material damage, whereas that portion which projected above the wall and to which the gases could obtain direct access was obviously damaged.

The beeches appeared to suffer the most, sycamores, elms, and oaks being more resistant. A certain amount of sulphuric acid vapour also escaped from the works from time to time, but not to anything like the same extent as the oxides of nitrogen. The sulphurous vapour would no doubt contribute to the damage, but this is more difficult to determine as sulphates occur naturally in all vegetation* whereas nitrates do not† though according to Wiley they occur in considerable quantity in the tobacco plant.‡ In this connexion it has been stated that the tobacco plant is particularly injured by nitric acid, and that next to all herbaceous plants, trees generally suffer.§

Our experiments were made on leaves which had been air dried in a room where they could not come into contact with nitric fumes.

Ten grams of the leaves, free from twigs &c., were placed in a clean dry stoppered bottle, 200 c.c. of distilled water was added, and the bottle and contents were gently agitated at frequent intervals for ½ hr., when the aqueous extract was poured off, the leaves remaining in the bottle were drained for a specified time, the drainings being added to the decanted liquid and the bulk made up to 200 c.c. Known quantities (generally 10 c.c.) were taken for the detection and estimation of nitrates, only those methods being used which were capable of estimating minute quantities of nitrates in the presence of comparatively large quantities of nitrogenous organic matter.

§ A. W. and M. W. Blyth, "Poisons." 1906 4th Ed., p. 110.

Phenolsulphonic acid method.—There was no difficulty in detecting the presence of nitrates, but for quantitative purposes the process was not satisfactory, the colour produced being of a much browner tint than that of the standard ammonium picrate solution, and when the solutions were allowed to stand for a short time a greenish tint began to develop which made comparison still more difficult.

Indigo method.—This was also found unreliable for quantitative purposes.

Brucine method.—The results quoted were all obtained by this method, which was found to be well suited for the purpose. The process is due to West Knights,[¶] and is based upon the well-known reaction of brucine with nitrates, a deep red colour being produced on evaporation to dryness in the presence of a small quantity of oxalic acid. The residue thus obtained is dissolved in a small quantity of water, the solution filtered, and the colour compared with that of a solution containing a known quantity of nitrate.

A standard solution of potassium nitrate is prepared by dissolving 0·721 g. in distilled water and making up to a litre: each c.c. of this solution is thus equal to 0·0001 g. of nitric nitrogen. 10 c.c. of the solution is evaporated to dryness on a water bath and 3 c.c. of a 1% solution of brucine in alcohol and 0·5 c.c. of a saturated solution of oxalic acid are added to the residue, which is again evaporated to dryness. A little distilled water is then added to dissolve the residue and the volume made up to 100 c.c. Each c.c. of this solution = 0·00001 g. of nitric nitrogen.

One example of the damaged leaves of a sycamore may be given. The extract from 0·5 g. of leaves was treated as described, the final solution being filtered to remove any calcium oxalate and then diluted to 50 c.c. in a Nessler cylinder; 7 c.c. of the standard red solution was required to match the colour given by 10 c.c. of leaf extract. Then $0{\cdot}00001 \times 7 \times 200 = 0{\cdot}014\%$ of nitric nitrogen.

The following is a list of results obtained:—

TABLE A.

			Nitric N. %	Nitric acid %
No. 1	Beech (damaged	.. .. ..	0·056	0·252
„ 2	Elm „	¼ mile from works	0·072	0·324
„ 3	Elm „	near to No. 2 ..	0·012	0·054
„ 3a	Sycamore „	Leaves fallen to the ground	0·060	0·270
„ 4	Beech „	.. .. ..	0·050	0·225
„ 5	Sycamore „	.. .. ..	0·084	0·378
„ 6	Ash „	.. .. ..	0·024	0·108
„ 6a	Grass „	From edge of a manhole from which nitric fumes escaped at intervals	0·032	0·144
„ 7	Beech „	.. .. ..	0·036	0·162
„ A	Beech (damaged side)	.. ..	0·018	0·081
„ A1	Beech (same tree as A, undamaged side) ..	.. ..	—	—

A sycamore, an elm, and an ash from the same estate, but some distance from the works and which from their position could not have been exposed to the nitric fumes, were all undamaged and did not contain any traces of nitrates. (These samples were taken in August, 1916.)

TABLE B.

Results in parts per 100. (Samples taken July, 1918.)
These trees are not included in Table A.

			Nitric N.	*Total acid.	Chlorine.	Sulphur trioxide.
No. 1	Sycamore	(damaged) ..	0·014	0·799	0·62	0·78
„ 2	„	(undamaged)..	—	0·517	0·38	0·46
„ 3	Elm	(damaged) ..	0·044	1·17	0·96	1·12
„ 4	Elm	(undamaged)..	—	0·90	0·68	0·38

* Total acid expressed in terms of sulphuric acid.

The damaged and undamaged sycamores were 12—15 yards apart, while Nos. 3 and 4 were from the same tree, No. 3 being exposed to fumes, No. 4 being protected by a wall.

In addition we have tested the leaves from elm, elder, hawthorn, and plane trees growing in Springfield Mount, Leeds, and from ash, beech, elm, and sycamore trees growing at Ilkley, and have in all cases proved the absence of nitrates. In none of the leaves, either damaged or undamaged, could we find any trace of nitrites.

¶ Analyst, 1881, 56-58.

DISCUSSION.

MR. W. McD. MACKEY suggested that the effect of fumes on a leaf would depend on the surface of the latter; he would expect a smooth leaf to be more immune than one with a rough surface. He asked if the shrivelling effect observed might not have been due as much to sulphur oxides as to the oxides of nitrogen.

MR. BURRELL, in reply, said that the difficulty with regard to sulphuric anhydride was that all leaves contained an appreciable quantity of sulphate, and no definite line could be drawn between the natural amount and an abnormal amount sufficient to cause damage. No such difficulty occurred with nitrates.

Communications.

THE ACTION OF HYDRAZINES ON CELLULOSE ACETATES.

BY W. LEIGH BARNETT, B.SC., A.I.C.

The object of this investigation was to determine whether phenylhydrazine and *p*-bromophenylhydrazine form any definite chemical compounds with cellulose esters, which compounds might be comparable with simpler hydrazones. Under normal conditions cellulose has not been known to react with phenylhydrazine to give well-defined products, owing no doubt to the inertness of the cellulose complex, and to the fact that it is insoluble in ordinary solvents which are used in the case of simpler ketones. Again, it is possible that the cellulose complex is held together by oxygen linkages, and until these linkages are broken and the cellulose complex degraded the ketonic or aldehydic groups cannot function as such. Consequently no phenylhydrazones of cellulose are formed by reason of the enforced inactivity of these latent groups. It was considered that the problem could be attacked by first of all forming cellulose esters, made by the author's method (J., 1921, 8 T), so as to ensure the minimum of degradation of the complex, and then treating these esters with the hydrazine. The fact that these esters are readily soluble in many solvents obviously simplifies the problem. It is clearly of importance that the cellulose esters utilised in this research should be made in such a way as to preclude the possibility of dissociation of the parent complex, otherwise the initial ester, being of lesser magnitude than the cellulose complex, would show an enhanced reactivity due to the degradation which it had undergone.

If dissociation of the cellulose complex, $(C_6H_{10}O_5)_n$, occurs, and if this is brought about by rupture at the oxygen linkages freeing more and more ketonic groups as the value *n* grows less, then at the same time there will be a progressive increase in the amount of phenylhydrazine reacting with the ketonic group to form hydrazone. Taking the case of cellulose triacetate, which can be written as $[C_6H_7O_2(CH_3CO_2)_3]_n$, and supposing for any value of *n* there be one ketone group only, the complex can be written in the form, $C_{6n}H_{7n}O_{2n-1}O(CH_3CO_2)_{3n}$, and the corresponding phenylhydr-

azone will be $C_{6n}H_{7n}O_{2n-1}C_6H_5NH.N(CH_3CO_2)_{3n}$. In the case of the *p*-bromophenylhydrazone the general formula will be similar as shown by $C_{6n}H_{7n}O_{2n-1}C_6H_4BrN_2H(CH_3CO_2)_{3n}$. The nitrogen and also the bromine content of these compounds will vary inversely as the value of *n*. Conversely, if by experiment the least amount of bromine, and nitrogen, be ascertained, and if these quantities be definite together with the properties of the specific compound under observation, irrespective of the mode of preparation, it should be possible to fix on a value for *n*, and hence get some indication of the molecular complexity of the cellulose complex.

The results obtained from a large number of experiments both with di- and triacetylcellulose, and also phenylhydrazine and *p*-bromophenylhydrazine, indicate that it is possible to obtain a series of definite compounds containing nitrogen (and halogen) in quantities corresponding with the amounts expected from cellulose acetates calculated according to the general formulæ given above, provided that the value *n* be chosen suitably. These hydrazones have definite melting points, and also exhibit the normal characteristics of ketose hydrazones. The experimental methods adopted were such as to eliminate the possibility of the purified products being merely adsorption products of the hydrazine by the cellulose ester colloid. Essentially the method consisted in treating a solution of the cellulose acetate in a suitable solvent with the hydrazine, under different conditions of temperature and time of duration of the treatment, followed by removal of the solvent and excess hydrazine, and then exhaustive purification of the product by repeated solution, precipitation, filtration, and washing, the number of re-precipitations of the substance depending on its properties.

The following solvents were employed for the initial solution of the cellulose acetate:—Aniline, chloroform, glacial acetic acid, *o*-toluidine, nitrobenzene, pyridine, and phenol. The cellulose acetates used were made by the author's method (*loc. cit.*), from filter paper, cotton wool, and bleached cotton yarn.

As important differences exist between acetylcellulose phenylhydrazones and the bromophenylhydrazones they will be treated separately.

Acetylcellulose phenylhydrazones.—It was found possible to obtain the same acetylcellulose phenylhydrazone starting from different cellulose triacetates, irrespective of the initial properties, and also of the mode of operation in the preparation of the hydrazones. The final products form, as a rule, amorphous powders, which may be coloured from a whitish-grey to a very pale yellow or light brown. All these substances are soluble in hot alcohol, but in different degrees. The solubility is apparently influenced by the solvent employed in the first part of the reaction. The temperature at which the treatment of the cellulose acetate with the phenylhydrazine is carried out has less influence on the nature of the product than the solvent, and to a lesser extent the time of heating. An important physical difference between the phenylhydrazones obtained from the triacetate from paper and cotton was noticed. If the product in the form of an amorphous powder, which is not perfectly freed from traces of alcohol used in the final washing in the purification process, be placed in an oven to dry at 100° C., the whole mass rapidly coalesces and assumes the appearance of a transparent yellow resin. These resinous masses are hard, brittle, and flaky. In alcohol they give solutions similar to shellac varnishes. Evaporation of the alcohol from thin films of the solution leaves hard, glossy, transparent, but somewhat brittle, films. Whether the product be in the form of an amorphous powder or resin, it possesses a well-marked melting point, at which unstable viscid brown liquids are formed. The melting points appear to be associated with the solubility in alcohol, and not with the complexity of the compound, as deduced from the nitrogen content. Thus the most soluble product obtained (1·02% N, m.p. 229° C.) was of the resinous type, and was made from a filter paper cellulose triacetate. The next in order of solubility had 4·16% N, m.p. 238° C. Several compounds less soluble in alcohol melted at 245° C., although the nitrogen content varied between 0·76 and 4·44%, the same samples giving concordant figures. The least soluble products melted about 262° C., the nitrogen content being 0·90—1·78%. All these compounds dissolve easily in acetone, giving clear solutions from which they can be precipitated unchanged by suitable means. This latter fact shows that there is no possibility of these substances being adsorption products, otherwise the acetone would react with the liberated phenylhydrazine in the usual manner.

In the case in which chloroform is used as a solvent for the cellulose acetate, followed by digestion with phenylhydrazine, the reaction is complicated by the formation of a crystalline substance which separates in very fine, glistening plates. This was found to be due to the action of the chloroform on the hydrazine. Steps had therefore to be taken to eliminate the possibility of contamination of the cellulose derivative by this crystalline substance, which was separated and investigated separately. (Details of this substance will be given in a separate paper.)

Experimental.—The method adopted consisted essentially in first dissolving the cellulose acetate in the chosen solvent, which was generally warmed to facilitate solution, and when complete solution had occurred the phenylhydrazine was added, after which the mixture was heated to the boiling point for known periods of time. The solvent was then removed by suitable means depending on its nature. In the case of chloroform this was effected by mixing with excess of water and distilling off the chloroform on a water-bath. In the case of aniline, nitrobenzene, etc., after mixing with water the excess of solvent was removed by steam distillation. The remaining products were filtered off, washed, pressed, and then repeatedly dissolved in hot alcohol (under a reflux condenser), followed by cooling to precipitate the substance in a fine powdery form, filtration, washing with alcohol, and then re-dissolving in more alcohol, and re-precipitation. This process was repeated until the melting point of the product was constant. Generally from eight to twelve re-precipitations from alcohol were employed, the number depending on the nature of the product, and its solubility in alcohol. In some cases it is necessary to use mixtures of alcohol and ether or of alcohol and water for the final stages in the purification.

TABLE I.

Nitrogen in phenylhydrazones from diacetates and triacetates.

	Diacetates. %	Triacetates. %
1.	8·33	7·48
2.	4·81	4·20
3.	3·38	2·94
4.	2·60	2·25
5.	2·12	1·83
6.	1·78	1·54
7.	1·55	1·33
8.	—	1·17
9.	—	1·04
10.	—	0·94
11.	—	0·86
12.	—	0·79

From Tables I. and II. it will be seen that the carbon and hydrogen content will vary to a far less extent than the nitrogen value for different members of the series contained therein. Hence in the greater number of preparations only the per

centage of nitrogen was ascertained. In a few doubtful cases the carbon and hydrogen figures were determined, and of these the hydrogen figure is the more reliable.

The experimental results are collected in Table II. for the sake of brevity. Table I. gives the nitrogen figures for the theoretically possible compounds from the di- and triacetates respectively for various values of n.

† F.P. stands for cellulose acetate from filter paper, B.C. that from bleached cotton, and C.W. that from cotton wool. Time=time in hours that mixture was actually heated. n is the value which is found to correspond with the nitrogen figure, from Table I. Form.—R=resin. P=powder. All samples marked P could not be induced to show the resinification phenomenon.

* The solution was allowed to stand for several hours after heating.

In determinations of the melting points of these substances the temperature must be raised rapidly, as is common in the case of phenylhydrazones of simpler compounds. They all show an initial softening about 12° C. below the actual melting point, when they decompose simultaneously. A marked shrinkage in volume accompanies the initial softening.

Acetylcellulose p-bromophenylhydrazones. — It was considered that these substances would possess more marked physical properties than the corresponding phenylhydrazones. They were made in a similar manner. The final products were amorphous powders, varying from almost white to dark brown in colour. No signs of resinification were observed in any case, even when cellulose acetate derived from filter paper was employed. Initial subjection of the filter paper before acetylation to vigorous chemical purification, such as treatment with bromine or chlorine, followed by sulphurous acid, and then washing until free from impurities, did not give rise to resinous products. The melting points of these substances are sharper than those of the corresponding derivatives from the same acetylcellulose and phenylhydrazine. Further, in most cases no pronounced preliminary darkening occurs before the melting point is reached, although decomposition takes place at the melting point. In most cases these substances melt at higher temperatures than the simpler acetylcellulose phenylhydrazones. At the same time, the solubility in alcohol is less than the corresponding solubility in the simpler series. As may be expected, the results of analysis, based on the bromine content, indicate that the reaction is a progressive one, the composition of the bromophenylhydrazone produced becoming simpler on prolonged treatment before the reaction is checked. The application of heat for a short time during the reaction causes a more rapid breakdown of the complex than occurs when the mixture is allowed to stand for some time without much heating. The degradation of the complex does not proceed to such an extent as in the case of the phenylhydrazones. This is shown by comparison of the bromine content as found with that possible calculated from the general formula for triacetate products, $C_{6n}H_{7n}O_{2n-1}Ac_{3n}C_6H_4BrN_2H$. This is indicative of a much further resolution of the cellulose acetate by phenylhydrazine than by *p*-bromophenylhydrazine. The difference of solubility of the products in alcohol also points to the same conclusion, for in general the greater the solubility the greater the degradation of the complex. Again, the melting points are higher, and in most cases are round about 287° C., and the subsequent thermal decomposition is similar to the mode in which degraded cellulose acetates decompose on heating. As the degradation of the complex increases so the melting points decrease, exactly as shown in the parallel case of the simpler hydrazones.

Experimental.—The method of preparation and purification was similar to that outlined for the acetylcellulose phenylhydrazones. The results obtained are shown in Table III.:—

TABLE III.

Ester.*	Solvent.	Time, hrs.	m.p.	Br % found.	Br% (calc.)	n	Colour
BCI	Aniline	48	243	1·07	1·085	25	L.Y.
FPS	Acetic acid	22	245	3·57	3·66	7	C.B.

THE EFFECT OF APPARATUS ERRORS ON THE ACCURACY OF VOLUMETRIC ANALYSES.

BY VERNEY STOTT, B.A., F.INST.P.

The object of the present note is to examine in detail how the results of volumetric analyses are affected by inaccuracies in the apparatus used. The errors due to other sources will be briefly indicated also. In attempting to arrive at a numerical estimate of the inaccuracy due to the errors in the apparatus involved it will be assumed that the apparatus used has the maximum errors permissible under the N.P.L. Class A tolerances,* and that the apparatus is used without applying any corrections to the nominal capacity.

Errors in preparation of a solution for analysis.

The usual procedure is to dissolve a known weight of the substance to be analysed (or the whole of one

* The tolerances allowed on Class A apparatus are given in a pamphlet, "Volumetric Tests on Scientific Glassware," published by the National Physical Laboratory in November, 1910.

constituent from a known weight of the substance) and to make up the solution to a definite volume in a measuring flask. We will assume that the flask used is inaccurate by an amount equal to the N.P.L. Class A tolerance. If the strength of the solution were to be calculated by taking the nominal capacity of the flask as its true capacity, then a percentage error would be introduced equal to the N.P.L. Class A tolerance expressed as a percentage of the nominal capacity of the flask. The Class A tolerances correspond on the average to an error of $\pm 0{\cdot}03_5\%$, assuming flasks of capacity 100 c.c. to 1000 c.c. to be used.

Errors in preparation of standard solutions.

(A) Where a pure chemical is available a known weight may be dissolved and the solution made up to a definite volume in a measuring flask. The error in such a case would therefore be $\pm 0{\cdot}03_5\%$, as above. This procedure is, however, not always possible, and other methods have to be adopted.

(B) *Standard acid solutions.*—The strength of standard acid solutions most frequently used is $N/10$. Such a solution may be prepared as follows: A solution which is approximately $N/1$ is first made. Then a weighed quantity (2 g. is a convenient amount) of pure anhydrous sodium carbonate is dissolved in any convenient quantity of water, and the volume of the acid solution required to neutralise this is determined by titration. The normal acid is then diluted to $N/10$. Assume 2 g. of sodium carbonate to be taken, and approximately 42 c.c. of the normal acid to be required to neutralise it. If the 42 c.c. were measured from a Class A burette it may be in error by $\pm 0{\cdot}04$ c.c., *i.e.*, by $\pm 0{\cdot}09_5\%$. The dilution to $N/10$ would probably be performed (I.) by delivering 100 c.c. of $N/1$ acid from a pipette into a 1000 c.c. flask; (II.) by delivering 100 c.c. of $N/1$ acid twice from a pipette into a 2000 c.c. flask; or (III.) by delivering 200 c.c. of $N/1$ acid from a pipette into a 2000 c.c. flask.

The errors would be:—

	I.	II.	III.
Possible pipette error ..	$\pm 0{\cdot}05$ c.c.	$\pm 0{\cdot}10$ c.c.	$\pm 0{\cdot}08$ c.c.
flask error ..	$\pm 0{\cdot}20$ c.c.	$\pm 0{\cdot}35$ c.c.	$\pm 0{\cdot}35$ c.c.
	$\pm 0{\cdot}25$ c.c.	$\pm 0{\cdot}45$ c.c.	$\pm 0{\cdot}43$ c.c.
i.e.	$\pm 0{\cdot}02_5\%$	$\pm 0{\cdot}02_2\%$	$\pm 0{\cdot}02_1\%$

The error in dilution may hence be taken as $\pm 0{\cdot}02_3\%$.

Combining this with the burette error, we obtain $(\pm 0{\cdot}09_5 \pm 0{\cdot}02_3)$, *i.e.*, $\pm 0{\cdot}11_8\%$, as the total possible error.

(C) Decinormal oxidising solutions may be checked directly against a known weight of sodium oxalate, and in this case there would be no dilution errors. For example, 0·5 g. of sodium oxalate would be oxidised by 74·6 c.c. of $N/10$ potassium permanganate solution. If the 74·6 c.c. were measured with a Class A 100 c.c. burette the possible error would be $\pm 0{\cdot}08$ c.c., *i.e.*, $\pm 0{\cdot}10_7\%$. With half quantities and using a 50 c.c. burette the percentage error would be the same.

(D) *Indirectly determined standard solutions.*—Some standard solutions can only be standardised indirectly against a chemical of known and very high order of purity. The following is a method of standardising a sodium thiosulphate solution which will serve as an example. A potassium permanganate solution standardised as above (and therefore liable to an error of $\pm 0{\cdot}10_7\%$ due to assumed inaccuracy of apparatus) could be used to liberate iodine from an excess of potassium iodide solution. The apparatus error involved would be that of the pipette used to measure the potassium permanganate solution. If a 50 c.c. pipette were used this error would be $\pm 0{\cdot}07\%$. The average percentage error for pipettes of capacity from 25 to 100 c.c. would be 0·08%. The error using a 50 c.c. pipette is therefore sufficiently typical. In titrating the liberated iodine against the $N/10$ thiosulphate about 50 c.c. of the latter would be required and be liable to an error of $\pm 0{\cdot}04$ c.c.

The total percentage error is therefore $0{\cdot}10_7 + 0{\cdot}07_0 + 0{\cdot}08_0 = \pm 0{\cdot}25_7\%$.

The mean of the errors in the above four cases (A—D), *i.e.*, $\pm 0{\cdot}12\%$, is very close to the values for B and C, which are cases of very frequent occurrence, and therefore, although the mean has in itself no particular significance, it will be convenient to use this figure as the percentage error in standard solutions when this value is required in considering errors in the various types of analyses dealt with below.

Errors in analyses of Type I.

When a known weight of substance is dissolved and the whole solution titrated against a standard solution, the error of the burette used for the titration is involved. Taking 30 c.c. as an average quantity of standard solution to be used and a 50 c.c. burette as the most commonly used size, we have a possible error of $\pm 0{\cdot}04$ c.c. on 30 c.c., *i.e.*, $\pm 0{\cdot}13_3\%$. To this must be added the error of the standard solution, viz., $\pm 0{\cdot}12\%$, and we thus obtain $\pm 0{\cdot}25\%$ as the total error due to inaccuracy of the apparatus used.

Errors in analyses of Type II.

In this case a solution is made up to a known volume and an aliquot portion taken for titration against a standard solution.

The errors in making up to known volume and taking an aliquot part vary from $\pm 0{\cdot}20_0\%$ with a 100 c.c. flask and a 10 c.c. pipette to $\pm 0{\cdot}05_7\%$ with a 2000 c.c. flask and 200 c.c. pipette. We may reasonably take $\pm 0{\cdot}10\%$ as the error arising in measuring off an aliquot portion. To this must be added the burette error in the titration and the error in the standard solution, and we thus get the total error as follows:—Pipette and flask errors, $\pm 0{\cdot}10\%$; burette error, $\pm 0{\cdot}13_3\%$; error in standard solution, $\pm 0{\cdot}12\%$; total, $\pm 0{\cdot}35_3\%$.

*Errors in analyses of Type III.**

This may be described as the excess method, and involves the use of two standard solutions.

Suppose A and B to be the two standard solutions and C the solution whose strength is required.

To take a particular case, suppose 50 c.c. of A is equivalent to 50 c.c. of B, and that when 50 c.c. of B is added to 50 c.c. of C. 30 c.c. of A is required to complete the neutralisation of B. Thus 20 c.c. of B is equivalent to 50 c.c. of C.

The errors involved are as follows:—The strength of the solution A added from the burette in the first case to 50 c.c. of B, and in the second case to 50 c.c. of B and 50 c.c. of C need not be known. The solution A simply serves to give the ratio 20 c.c./50 c.c. obtained from the burette readings. This ratio may be in error by 0·2%. The error in taking an aliquot portion of C would also be involved, and the error in the assumed strength of B, and in measuring the amount of B taken from the test. The total errors would therefore be:—Error in ratio of burette readings, 0·2%; in making up C and taking a portion, 0·1%; in measuring B (average pipette error), 0·08%; in standard B, 0·12%; total, 0·50%.

If C were a solution of the whole of a constituent from a weighed portion of a substance, *e.g.*, a solution of the phosphorus from a weighed quantity of steel, then the error in taking an aliquot portion would not arise and the above value would reduce to 0·40%.

* The bismuthate method of determining manganese in steel is an example of Type III.

Summary of errors in typical cases.

The errors in the cases considered are summarised in the table below:—

	Type I.	Type II.	Type III.
Standard in error by ±0·03%	±0·16%	±0·26%	±0·41%
" " " ±0·11%	±0·24%	±0·34%	±0·49%
" " " ±0·26%	±0·39%	±0·49%	±0·64%

The mean of the values given in the above table is ±0·38%. The value ±0·4% may therefore be taken as an average value for the greatest error which may arise in a volumetric analysis due solely to inaccuracies in the apparatus used, it being assumed that the apparatus used has the maximum errors allowed under the N.P.L. Class A tolerances.

Significance of above error.

The figure ±0·4% represents the possible range of the total error due to inaccuracies of the apparatus used, and not the probable error in any particular case. The figure assumes all errors to be cumulative, whereas they may be compensating, *i.e.*, the figure relates to the worst case which may arise.

The probability of the errors being cumulative as regards sign is $1 \div 2^{n-1}$ where n is the number of pieces of apparatus used. For example, using a flask, pipette, and burette, the probability of the errors being cumulative is ¼. Hence, unless more than five or six different pieces of apparatus are involved, the probability of the errors being cumulative as regards sign cannot be considered small.

The probability of the errors in the apparatus having the maximum value allowed under the Class A tolerances cannot be assigned a definite value. It should be noted, however, that the Class A tolerances represent a high standard of manufacture, and that in ordinary commercial grade apparatus larger errors than the maximum allowed under the above tolerances are quite likely to occur.

Another important point is the significance which the above error would have in the final form in which the results of the analysis are expressed. In a large number of instances the object of a volumetric analysis is to determine the percentage of one constituent of the substance under examination. If there is x% of the constituent present, and the error in its determination due to the cause considered above is n% of that constituent, then the error expressed as a percentage of the whole substance is $nx/100$%. Thus on a 10% constituent the average maximum value of 0·4% derived above for the error in the volumetric determination would be 0·04% when expressed as a percentage of the whole substance.

The same matter may be viewed in a slightly different manner as follows:—If a 10% constituent is determined volumetrically and the result is required correct to the first decimal place, then the total errors from all causes should not exceed ±0·05% of the whole substance, *i.e.*, 0·5% of the 10% constituent.

We have seen that the errors due simply to the apparatus used being inaccurate to the extent of the N.P.L. Class A tolerance may amount to 0·4% of the constituent, taking an average of the maximum values.

It is clear, therefore, that when a constituent is to be determined to an accuracy corresponding to 0·5% or even to 1% of the percentage of the constituent present, the errors of the apparatus used are a factor requiring careful consideration.

Other sources of error.

(1) *Errors in weighing.*—These should be negligible if proper precautions are taken.

(2) *Errors of manipulation.*—Such are: (*a*) incorrect setting of liquid meniscus on graduation marks of pipettes and flasks or incorrect reading of position of liquid surface in burette; (*b*) not strictly adhering to standard methods of delivering liquid from pipettes and burettes; (*c*) loss of liquid by splashing etc.

The errors under (*a*) may be placed at approximately from 1/5th to 1/10th of the N.P.L. Class A tolerances. The errors under (*b*) are not likely to be more than 1/4th the N.P.L. Class A tolerances when standard apparatus is used. The errors under (*c*) should, of course, be negligible.

(3) *Errors due to uncertainty of end-point.*—This varies with the method of observing the end-point. With ordinary indicators as generally used, the value 0·03 c.c. should cover this source of error.

(4) *Errors due to temperature differences.*—If standard solutions are made up within one or two degrees of 15° C., and solutions are allowed to assume room temperature before titration, no serious errors need arise from this cause.

(5) *Chemical errors.*—Under this heading come such sources of errors as the partial oxidation of ferrous iron to the ferric state before the addition of the standard oxidising solution, the incomplete separation of closely allied elements, etc. Such sources of error are of a different nature from those dealt with above, and relating as they do to particular methods do not properly arise in considering errors common to volumetric analyses in general.

(6) *Uncertainties in the accepted values of the atomic weights.*—These again are of a particular nature beyond the scope of the present paper.

General conclusions.

Excluding such causes as (5) and (6) just given, it is interesting to frame some estimate of the probable percentage error arising from the other causes just enumerated. No exact figure of general application can be given. In the opinion of the author a minimum estimate would be 0·4%. To assign a maximum figure is more difficult. Twice or three times the minimum would be a fairly reasonable estimate, but the question is one on which it is impossible to be precise.

Finally it has been shown that 0·4% may be taken as a fairly representative average of the maximum errors which may arise in volumetric analysis due solely to apparatus errors when using apparatus accurate within the N.P.L. Class A tolerances, but used without applying corrections.

A more debatable conclusion is that a minimum estimate of the errors from other sources is also approximately 0·4%.

The National Physical Laboratory.
January, 1921.

THE EROSION OF BRONZE PROPELLERS.

CONTRIBUTION TO DISCUSSION.

Mr. WILLIAM RAMSAY (of Messrs. Cammell Laird and Co., Ltd., Birkenhead) wrote that Dr. Silberrad's paper (J., 1920, 38 T) was of special interest to him as he had been engaged on the same work for some twenty years. Although Dr. Silberrad and the "Propeller Committee" appeared to be satisfied that the cause of the defect has been definitely settled as a purely mechanical action, others were not so convinced that the correct explanation had been given. The "Propeller Committee" had consisted of Sir Charles Parsons and a number of engineers and naval officers who, although of very high rank in their own professions, were hardly fitted to decide on a

metallurgical or chemical question. The only other member who could deal with the matter in an authoritative manner had been Prof. H. C. H. Carpenter. On the strength of a number of somewhat unconvincing experiments the Committee had decided that the defect was due to water-hammer action, the metal being broken away by impact and not by frictional wear or erosion. However weak their experimental evidence had been in favour of water-hammer action, it had certainly proved the erosion theory to be a fallacy.

Dr. Silberrad's claim that his alloy had overcome the defect was not, in his opinion, fully proved, his (the writer's) own experience being that such propellers were no better than those made of the old manganese brass. In his article on the subject published in "Engineering," May 24, 1912, several photographs of the defect appeared, all of which had been taken from blades of the Silberrad alloy, and a large stock of such propellers had been discarded as unsafe. It was not safe to rely on the presence or absence of copper concentration on the corroded surfaces for evidence of chemical action. In the conditions under which high-speed propellers worked such removal of zinc or copper concentration was impossible. Some recent work of his own had shown that this phenomenon was entirely due to redeposition of copper from the corrosion product, and if the latter were swept away as formed no redeposition of copper took place.

He had carried out many erosion tests on similar lines to those of Dr. Silberrad, but using a high-pressure jet of Mersey water. In no case had he been able to obtain more than a slight roughening of the disturbed surface layer of metal; the extent of the action appeared to depend very largely on the manner in which the surface of the metal was prepared. If, however, the jet was made the negative and the metal the positive of a circuit supplying a small current such as might exist between stressed and unstressed metal, interesting results were obtained. At low water pressures the metal became coated with corrosion product, and the current fell off almost to nothing in a short time. At a higher pressure the corrosion product was washed away, and the metal (brass) was seen to be coated with redeposited copper. At still higher pressure this copper was removed and the corroded surface became bright and of the natural colour of the metal. Further, the loss in weight was invariably greater than that demanded by the current supplied; in one case the excess corrosion amounted to over 800%, though as a rule it was from 50% to 200%. Specimens corroded in the above manner reproduced in miniature all the features of a corroded propeller blade. No distinction could be drawn between α-brass and β-brass or one containing both phases. Pure metals behaved similarly, and, as one might expect, aluminium and zinc appeared to suffer most. Further investigation into the matter was required, but it appeared to him that such combined action might be sufficient to account for propeller deterioration.

Dr. Silberrad's tests on stressed and unstressed brass showed a small but consistently greater loss on the stressed material. A high-speed propeller blade, however, instead of being stressed four times per minute, probably suffered alternating stresses of the order of 800 per minute and possibly a much higher frequency, and had Dr. Silberrad or the "Propeller Committee" approached these conditions in their experiments it was possible that their results and conclusions might have been very different.

The practice of backing metal with soft solder for sectioning for micro-examination was, in his (the writer's) experience, open to objection, and he was surprised that Dr. Silberrad had not found many more distorted α-crystals. There was a growing suspicion among micro-metallurgists that even such a mild process as polishing a comparatively soft metal such as brass distorted the surface layer of crystals to some slight extent even under the amorphous polish layer. This was sometimes seen in an exaggerated form at the filed or sawn edges of a section. Embedding in solder, Wood's alloy, or in electro-deposited copper did not entirely prevent this, and crystals were frequently torn completely out at the junction of the two metals. The presence of distorted crystals at the edge of a fracture or a surface such as Dr. Silberrad had examined should therefore be accepted with certain reservations.

When the turbine had first been used for marine propulsion, owing to the high shaft speed and other considerations, it had been considered necessary to cut down blade weight to the lowest limit, the result being that at top speeds (about 800 revs. per minute) considerable "whipping" of the blade had ensued. Whether this was the cause of the trouble or not was still doubtful, but the use of stiffer blades had reduced the defect and, he understood, eliminated it in some cases. The present tendency to increase efficiency by reducing shaft speed by the intermediary of single or double reduction gear and stiffer propellers had practically removed the trouble, and to this extent The Manganese Bronze Co. and other equally good propeller founders might fairly claim that their alloys were erosion-proof.

The references to Sir William Ramsay called for some explanation. Sir William admittedly had not been an authority on the subject, and had intervened simply because someone had attributed the present writer's views on the subject to himself owing to their names being the same. The opinions which he had volunteered as to the universal use and success of the new alloy had been formed entirely on Dr. Silberrad's statements and not from first-hand knowledge of the subject. The continued use of Sir William Ramsay's name in that connexion therefore appeared to be unnecessary.

Joint Meeting of the Society of Chemical Industry and of the Institution of Mechanical Engineers.

Held at the Institution of Mechanical Engineers on March 4, 1921.

DEGASSING AND PURIFICATION OF BOILER FEED-WATER.*

BY PAUL KESTNER.

(*Abstract.*)

The problem of feeding boilers with water in such a way that they will run for long periods under steam without scale or corrosion has not been completely solved up to the present. The old lime and soda purifying apparatus has been improved and reduced in size, and heat has been applied to accelerate the process, but even with these improvements some kinds of water have proved refractory, scale being formed, or in some cases a concentrated solution of soda being produced in the boiler. A process has, however, been devised which prevents the formation of mud and incrustation completely. It consists of continuous blowing-down, used in conjunction with the hot purification process. Hot purification processes result in increased speed of reaction, more rapid evolution of dissolved gases, diminished viscosity of the water (resulting in more rapid settling of the precipitate), decomposition of alkaline-earth bicarbonates, and decreased solubility of calcium sulphate.

The usual method adopted to remove the sediments from boilers is to blow off the water periodically, but this necessarily involves loss of heat. To be effective, blowing off must take place to the extent of a large actual quantity of water, though the amount is small in proportion to the total contents of the boiler. In the continuous blowing down process, instead of sending the blow-off direct into the drain a relatively small quantity is removed from the boiler continuously at its lowest point and is passed through a feed-water heater of the direct contact type where it gives up its heat, the mud being deposited in a reservoir below the heater; the water in cooling loses a certain proportion of the salts which had been retained in solution and is then mixed with the feed-water and returned to the boiler. For example, the boiler may be blown down to the extent of 20% of its contents in an hour, *i.e.*, its contents are renewed every five hours; this ensures the elimination of all mud that has been produced before it has had time to accumulate. When the feed-water is purified by means of sodium carbonate, this reacts with the calcium bicarbonate, forming sodium bicarbonate, which is decomposed in the boiler into carbonate; a certain amount of sodium hydroxide is also formed in the boiler as a result of the hydrolysis of the sodium carbonate. In the continuous blowing down process, therefore, the feed-water is continuously supplied with a solution of sodium hydroxide and carbonate. If the quantity of water removed from the boiler in a given time is calculated so that it contains the quantity of soda necessary for the purification of the water entering the boiler in that time, it will not be necessary to add any sodium carbonate to remove the temporary hardness of the water.

The apparatus illustrated in Fig. 1 has been devised to use a blow-down on the described principle. It consists of a steam separator, S, which the blow-down enters in the form of a mixture of steam and water. The liquid from the blow-down falls into a central reservoir, P, in which it gives up its heat to the water surrounding it in the annular chamber, B, into which it is decanted. The steam from the blow-down rises in the reheater, R, in which it heats the feed-water, which thus loses a part of its bicarbonate. The heated water falls through the tube, T, and mixes with the blow-down as it leaves the central chamber, and then rises in the annular chamber, B, in which precipitation and settling take place. The purified water then passes through the filter and enters the boiler. The soda is distributed in the apparatus by means of a water meter, J, which admits it in proportion to the new water (make-up feed). The valves, V and V[1], allow the mud to be separated.

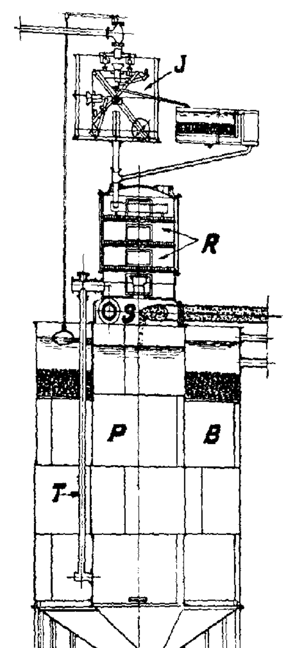

FIG. 1.

The blow-down must be arranged at the lowest possible level on the boiler without risk of emptying it. A simple arrangement (Fig. 2) is recommended by which, when the water of the boiler falls below a certain level, the siphon action of the blow-off is broken. At this moment steam leaves by the inlet and gives warning by sounding a whistle. In any case it is impossible to empty the boiler by the continuous blow-down. On the pipe of the continuous blow-down and the outlet from the boiler a reducing valve is placed, which reduces the pressure of the blow-down from that of the boiler to a pressure of 1—2 kg. per sq. cm. (15—30 lb. per sq. in.) before it enters the purifier. A meter, fitted with a regulating valve, is placed at the outlet of the boiler.

* The full paper will appear in an early issue of the Proceedings of the Institution of Mechanical Engineers.

The proportions of the blow-down are calculated according to the temperature to be maintained in the purifier, and the rate of blow-down depends on the working pressure of the boiler. The temperature at which purification is effected should not be less than 70° C.

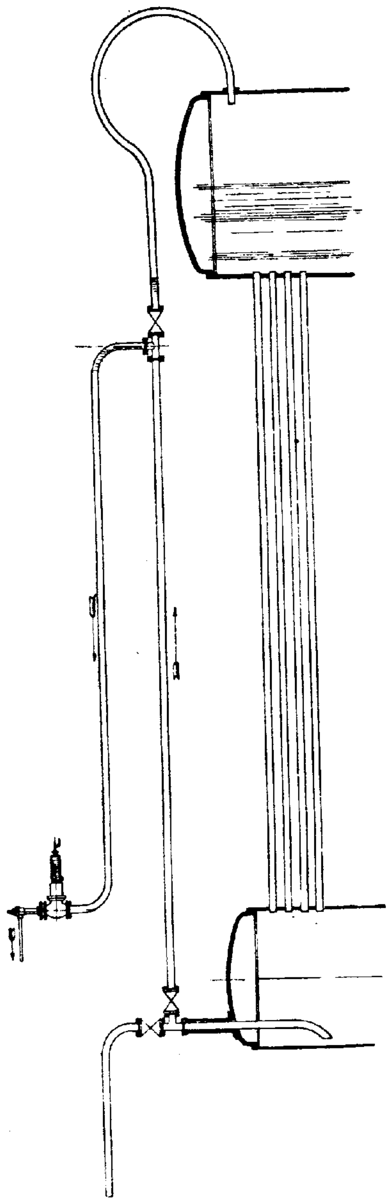

Fig. 2.

In central stations using distilled water, small amounts of soluble salts are carried over by entrainment, so that the salts gradually become concentrated in the water. Boilers working with distilled water therefore require to be blown down occasionally, the amount removed being usually 1—2 %, which is replaced by distilled water. Even when an evaporator is used the continuous blowing-down method can be adopted; a certain amount of saline or impure water can be drawn from the boilers and passed into the evaporator, which returns it to the boiler after it has been freed from the greater portion of its salts. By means of continuous blowing-down, in conjunction with degassing, a complete closed water circuit can be established in a central station using distilled water.

In the case of boilers using distilled water corrosion can only be produced by oxygen dissolved in the feed-water and set free in the boiler, and the effect is greater with intermittent working.

In the case of boilers using purified water other factors have to be considered before coming to a conclusion. The corrosive effect of saline solutions increases in proportion to the concentration up to a critical point at which it attains a maximum; the effect then decreases rapidly as the concentration increases. In practice, after a few hours, a boiler using purified water will have already attained a concentration fully one hundred times the critical amount, so that corrosion cannot be attributed to this cause. Electrical action may have some influence on corrosion, but it is not of great importance. Electrolytic dissociation occurs much more easily in a dilute than in a concentrated solution, and is of little importance in connexion with corrosion.

Hydrolysis may have more important effects, particularly in the case of magnesium chloride, which gives rise to the production of hydrochloric acid. Fortunately, this salt only occurs occasionally, and its effects are sufficiently well known for special care to be given where it is present. Carbon dioxide alone has only feeble action on iron, but in presence of oxygen the metal is attacked much more rapidly. Oxygen comes into play still further when the water contains salts capable of combining with oxygen and forming unstable oxygen compounds which can part with their oxygen to form other oxides.

Thus it appears that it is the solution of atmospheric oxygen in water that is the chief cause of corrosion, whether the feed is distilled water or purified water. This is supported by the fact that corrosion is often more serious in boilers using distilled water, in which dissolved oxygen can be the only agent, than in boilers using purified water. The remedy is simple, namely, the elimination of the dissolved oxygen.

The solubility of air in water follows Henry's law. At ordinary temperatures and pressures 18 c.c. of nitrogen and 35 c.c. of oxygen form saturated solutions with 1 litre of water. The quantities of each dissolved from air are therefore: Nitrogen: $0.8 \times 18 = 14.4$ c.c.; oxygen: $0.2 \times 35 = 7.0$ c.c. The air dissolved in water will therefore contain, roughly, 33% of oxygen. Laboratory tests have shown that the quantity of oxygen dissolved in water varies slightly with the nature of the water, and soft water absorbs more than fresh water, and soft water more than hard water. Distilled water absorbs 7·8 c.c. per litre at 20° C., 2·1 c.c. at 100° C. The water supply of Paris contains 6·06 c.c. per litre at 20° C., 4·3 at 55° C., and 2 c.c. at 100° C.

When water is heated supersaturation occurs. No gas is evolved up to a temperature of 75° C. Air is only driven off continuously when the water is agitated continuously from the commencement of heating. When water that has been boiled is cooled the inverse takes place; a litre of water absorbs, for instance, 2·3 c.c. at 44° C. and 3 c.c. at 20° C. If the water is agitated in air the false state of equilibrium is disturbed, and the water becomes saturated up to 6 c.c. of oxygen. The water resulting from the condensation of steam in the air contains 4 c.c. of oxygen per litre at 60° C. The same quantity of water of condensation exposing only a small surface to the air contains only 3 c.c. of oxygen per litre at the same temperature.

The determinations of dissolved oxygen have been made by the following modification of Winkler's method: The water is introduced into a 2-litre flat-bottomed flask through a tube dipping into a small quantity of paraffin; 1 g. of manganese sulphate is added and the flask is immediately closed by a rubber stopper fitted with a funnel having a stop-cock and a glass tube connected by rubber tube to another glass tube of larger diameter, carried on a stand. It is possible, by raising or lowering the tube, to change the pressure in the flask and to cause liquid contained in the funnel to be drawn into the flask. When the manganese sulphate is dissolved, 5 c.c. of sodium hydroxide solution is introduced through the funnel and the flask is shaken. After a quarter of an hour the absorption of oxygen by the manganous hydroxide is complete. Two c.c. of a 50% solution of potassium iodide (free from iodate) is introduced through the tube fitted with the funnel, followed by 20 c.c. of concentrated hydrochloric acid. The flask is shaken until the precipitate has dissolved and the amount of iodine liberated is determined by titration with standard sodium thiosulphate, preferably of such strength that 1 c.c. = 1 c.c. of oxygen.

The removal of the oxygen dissolved in water may be effected either by physical methods or by chemical methods, or by the two combined. The principal physical methods are agitation of the water, heating, and reduction of pressure. These three methods may be used either separately, or in the majority of cases, in combination. Of the chemical methods the only one to be considered is the action of highly oxidisable iron, which absorbs the oxygen from the water before entering the boiler.

Agitation of the water is used in various appliances in the form of fine spraying or circulation through channels of varying section, or by passing the current of water over an uneven surface. These can only have the effect of preventing supersaturation at the particular temperature and pressure. Even if the temperature of the water is raised to 100° C. the solubility of the gases cannot be neglected. Heating, however, produces a great improvement in the condition of the water entering the boiler. A vacuum would give better results still if it could be used at a very high temperature, but the vacuum cannot be very high, otherwise the water would boil. A large German company which makes an apparatus using these three methods simultaneously states that water treated by this process still contains some milligrams of oxygen that cannot be removed by a very high vacuum and by reheating. Nevertheless, the physical removal of gases diminishes the percentage of oxygen in the feed-water and retards the corrosion.

All chemical methods of removal of gases in actual use consist in passing the water over iron. If the iron has a sufficiently large surface, if it is of a kind readily oxidised, and if the water is circulated sufficiently slowly, all the oxygen can be eliminated.

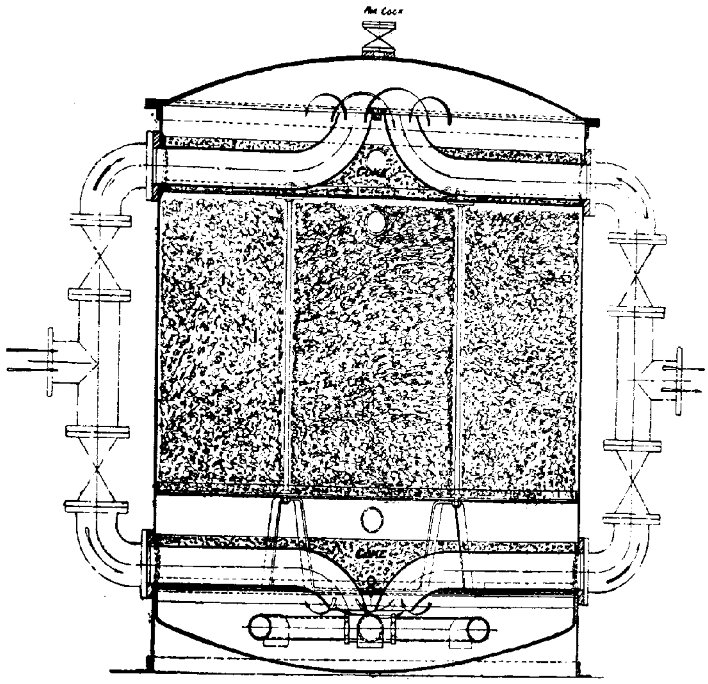

FIG. 3.

Laboratory experiments have shown that manganese accelerates the oxidation of iron, and a suitable manganese cast-iron for the purpose has been found.

In commercial appliances, when the coating of oxide becomes very thick, the removal of the oxygen may become considerably slower, but under the most unfavourable conditions water leaving such apparatus is found to contain less than 0·5 c.c. of oxygen per litre.

To avoid the retardation of the oxidising process by the deposit on the iron the Kestner Co. has designed an apparatus based on the observation that if the oxidised iron is allowed to remain at rest for a day the red deposit will become greenish-black owing to the reduction of the ferric hydroxide by the iron. This reaction takes place in the middle

of the reducing agent—that is, in the presence of iron and in the absence of oxygen. The product is easily removed from the iron by washing, and, moreover, is capable of further absorbing oxygen to form ferric hydroxide.

The Kestner apparatus (Fig. 3) consists of a column of iron turnings placed between two filters with an intake and outlet for the water at each end of the apparatus, in such manner that the direction of flow of the water can be reversed at regular intervals, and an arrangement for allowing steam to be admitted at the base for cleaning.

The column of turnings is of such quantity that one-half only is in action, and that the gases are removed when the water has reached half the height. At the end of the day the direction of flow is reversed. The consumption of iron turnings varies from 1 to 3 g. per cb. m. of water.

Whatever may be the method employed for removing the gases, it involves a circuit of water closed from atmospheric contact if it is to give a large output. It is therefore advisable that the tanks in which the water is retained should be as well enclosed as possible, and that on the whole pipe system there should be a small positive pressure.

In such a system the only place at which the entry of air should be possible is the condenser in which the vacuum is produced. The tightness of the condenser should therefore be very carefully tested, and the water should pass through the gas remover immediately before entering the boiler.

The study of continuous blowing down and of degassing has led to the conception of a complete circulation system for a central station using distilled water, in which one boiler evaporates the purified water coming from the purifier and supplies steam that passes with that generated by the other steam boilers to the steam main. The steam passes through turbines, is condensed, and re-enters the boilers as distilled water after it has passed through the degassing apparatus. All the boilers are blown down, and the amounts blown down are passed collectively through the purifier. The purified water is returned to the distilling boiler after it has passed through a special degassing appliance.

The boiler containing the water to be purified thus furnishes the supply to the boilers working with distilled water in the form of steam. It is only necessary to provide an overflow reservoir to enable any excess of purified water to be re-introduced into the circuit if such excess should be produced. All the boilers can be fed either with purified water or with distilled water, which enables any desired boiler to be used for distilling.

DR. H. W. BROWNSDON IN THE CHAIR.

THE PREPARATION OF ZIRCONIA FROM BRAZILIAN ORE AND A NEW METHOD OF DETERMINATION.

BY E. C. ROSSITER, A.C.G.I., F.I.C., AND P. H. SANDERS, A.I.C.

In the extraction of zirconia in a pure state from its ores one of the chief difficulties is the complete separation from iron and alumina. This paper describes a simple method for this separation and one which has been found to give practically quantitative results.

The method is based on the precipitation of the zirconia as a basic sulphate in which the ratio of zirconia to sulphuric acid is expressed by the formula $5ZrO_2,2SO_3$. A similar method has been proposed by K. Leuchs (G.P. 285,344, 1915) in which a basic sulphate of the formula $7ZrO_2,3SO_3,14H_2O$ is precipitated; Leuchs has modified this method (G.P. 295,246, 1916) so as to obtain a crystalline basic sulphate of the formula $3ZrO_2,2SO_3,6H_2O$. Both these products are claimed to be free from iron, but the yield is not stated. A similar method is described by the Pennsylvania Salt Manufacturing Co. (E.P. 153,113) in which a crystalline basic sulphate of the composition $5ZrO_2,3SO_3,13H_2O$ is obtained by adding the requisite proportion of sulphuric acid to a solution of the oxychloride; this basic sulphate is claimed to be substantially free from iron, titanium, and silica, but again the yield is not stated.

The ore used in the present investigation was from Brazil; it was ground fine in a porcelain ball mill before being used; during the grinding it was found that about 50% was much softer than the remainder and this was separated; on further grinding a small residue amounting to 0·8% remained unground. These three portions were analysed separately and gave the following figures:—

Analysis of the ore.

	Softer portion.	Hard portion.	Very hard residue.
ZrO_2	65·00	75·10	74·30
SiO_2	24·48	18·50	17·28
Fe_2O_3	4·90	1·75	4·80
Al_2O_3	4·30	4·05	2·70
Loss on ignition ..	1·25	0·50	0·50
	99·93	99·90	99·58

The ore also contained traces of titanium and manganese and gave a slight indication of thorium.

When this ore is extracted with hydrochloric acid for 3 days at room temperature only 41% of the iron and alumina is dissolved. When extracted at 100° with hydrochloric acid only 45% of the iron and alumina is dissolved and 0·25% of the zirconia.

Decomposition of the ore.

Two methods of decomposing have been examined, namely fusion with caustic soda and fusion with acid sodium sulphate (nitre-cake).

Fusion of the ore, previously ground to flour fineness, with its own weight of caustic soda at a final temperature of about 600° C. yields a product which, after extraction with hot water, is soluble in hydrochloric acid to the extent of 80% of the ore. Fusion of the ore with four times its weight of nitre-cake yields a product which on extraction with water yields a solution containing 50% of the ore.

Since, as will appear later, it is necessary to obtain the zirconia in solution as oxychloride in order to separate it completely from the iron and alumina, fusion with caustic soda is preferred. 50 g. of the zirconia ore is mixed with 50 g. of caustic soda and fused in an iron crucible; foaming occurs and the mixture is continually stirred until it becomes a granular powder; the temperature is then raised to just visible redness. The fusion takes 2 hrs. The product is thrown hot into 1½ l. of water, filtered, and the residue washed free from alkali. The insoluble residue is then treated with hydrochloric acid and the mixture evaporated to dryness on the water bath. The product is then extracted with hot water and filtered. The insoluble residue after the fusion process amounts to 19—20% of the ore used, and contains 61·55% ZrO_2, 29·32% SiO_2, 1·10% Fe_2O_3, 1·80% Al_2O_3, 5·90% loss

on ignition. The solution contains zirconium oxychloride, and iron, alumina, titanium, manganese, etc.

Precipitation of the zirconia.

The solution of the chlorides is diluted to 1½ l., treated with a slight excess of sulphurous acid over that required to reduce the iron salts (about 100 c.c. of saturated SO_2), and heated to boiling. $N/1$ Sulphuric acid is then gradually added in amount equal to that theoretically required to replace the chlorine in the oxychloride or until the mixture becomes quite thick; after a short time the whole of the zirconia is deposited as basic sulphate. This precipitate is easy to filter, and settles rapidly; it is, however, very bulky, and we prefer to wash it by decantation. Five washings by decantation in a glass cylinder of 6 l. capacity reduce the soluble impurities to 0·3% of the amount originally present. The precipitate is then drained on a filter. The wet precipitate gives only the faintest indication for iron when tested with thiocyanate, and therefore contains less than 1 part in 100,000.

To obtain zirconia from the basic sulphate it may be either dried and ignited, or suspended in water, treated with alkali, and the hydroxide washed, dried, and ignited. The zirconia obtained contains 98—99% ZrO_2, the remainder being silica and a small quantity of alumina. The above precipitation as basic sulphate is practically quantitative, and affords a ready means of determining zirconia in the presence of iron and alumina.

Zirconia is precipitated from the boiling solution of its oxychloride by sulphuric acid alone, and also by sulphurous acid alone, but the precipitates are usually very difficult to filter and wash, and in no case have we been able to obtain a complete precipitation under these conditions. The exact action of the sulphurous acid has not been determined; it was added in the first instance to prevent the precipitation of iron, which always comes down in small quantity with the zirconia in the absence of sulphurous acid.

Properties of the basic zirconium sulphate.

The basic zirconium sulphate when dried at room temperature or at 100° C. has the appearance and colour of clear amber. The sample dried at room temperature contained 51·92% ZrO_2, 13·53% SO_3, and 34·53% H_2O, corresponding with the formula $5ZrO_2,2SO_3,22{\cdot}6H_2O$. The sample dried at 100° contained 65·36% ZrO_2, 17·03% SO_3, and 17·80% H_2O, corresponding with the formula $5ZrO_2,2SO_3,9{\cdot}3H_2O$. It loses water progressively as the temperature of drying is raised. After drying at 100° it is easily soluble in concentrated sulphuric acid, slightly soluble in hydrochloric acid, and completely decomposed by prolonged boiling with sodium carbonate or ammonia. When ignited it blackens and is decomposed to the oxide. Before drying it is easily and completely soluble in hydrochloric acid, and when this solution is evaporated on the water-bath crystals of zirconium oxychloride are obtained, the mother liquid containing zirconium sulphate.

The hydroxide prepared by suspending the undried basic sulphate in ammonia is easily soluble in hydrochloric acid, and this solution when concentrated on the water-bath and allowed to crystallise yields the oxychloride $ZrOCl_2,8H_2O$, crystallising in slender needles. An analysis of this oxychloride gave 38·20% ZrO_2, 21·87% Cl_2, whereas the formula requires 38·12% ZrO_2, 22·12% Cl_2.

The basic zirconium sulphate described above has all the properties of the 5:2 basic zirconium sulphate described by Rodd (Chem. Soc. Trans., 1917, 111, 396), except that the hydrate when dissolved in hydrochloric acid yields the normal oxychloride. No trace of Rodd's 5:4 basic zirconium chloride was observed. Rodd also describes a basic sulphate obtained by adding sulphuric acid to a dilute solution of zirconium oxychloride previously boiled for 6 hrs.; this basic sulphate on analysis gave figures corresponding with those of the 5:2 basic sulphate, but after drying the salt was insoluble in sulphuric acid and was unattacked by ammonia, and is therefore different from the 5:2 basic sulphate described above, and also from Rodd's 5:2 basic sulphate.

Attempts to make Rodd's 5:4 basic zirconium chloride according to the method described by him always resulted in obtaining the ordinary zirconium oxychloride $ZrOCl_2,8H_2O$. Nor were we able to prepare a 5:2 basic sulphate which was different from that described above.

The determination of zirconia in the presence of iron and alumina.

Since the precipitation as basic sulphate described above was apparently quantitative, this reaction was examined to determine under what conditions it could be used in controlling the process of manufacture. Tests on a solution of zirconium oxychloride of known strength indicated that in order to obtain quantitative results, 7 c.c. of sulphurous acid solution and 2 c.c. of $N/1$ sulphuric acid should be used for each 0·2 g. of ZrO_2, and that the solution should be diluted to at least 150 c.c. for each 2 c.c. of sulphuric acid. The difficulty to be overcome in the presence of iron is the quantity of sulphuric acid formed in the reduction of the ferric salts to ferrous by the sulphur dioxide. Good results were obtained in the presence of iron in the proportion of 1 part of Fe_2O_3 to 3 parts ZrO_2 by proceeding as above and, by modifying the method, complete separation from quantities of iron oxide up to 3½ times that of the zirconia. Attempts were made by neutralising the solution with ammonia after the reduction, but the results were high on account of some iron being precipitated along with the zirconium basic sulphate.

By the following method, however, good results were obtained. The solution used contained 0·1906 g. ZrO_2 and ferric chloride equivalent to 0·7 g. Fe_2O_3, diluted to 150 c.c.; 25 c.c. of sulphur dioxide solution was added and the mixture boiled until the iron was reduced. It was then neutralised with ammonia, 10 c.c. of sulphur dioxide solution and 2 c.c. of $N/1$ sulphuric acid added, and the liquid again boiled. The precipitated basic sulphate was filtered off, washed, and redissolved in hydrochloric acid. This solution was evaporated just to dryness to remove excess of acid, the residue dissolved in water, and the zirconia again precipitated with 10 c.c. of sulphur dioxide solution and 2 c.c. of $N/1$ sulphuric acid. The ignited precipitate weighed 0·1900 g. and was quite white (error, 0·31%).

With much larger proportions of iron the method does not give good results since the basic sulphate is somewhat soluble in the ammonium sulphate and chloride formed during the neutralisation.

Research Laboratories,
The British Cyanides Co., Ltd.,
Oldbury.

Discussion.

Mr. Bradford said that the method appeared to have some points of resemblance with the patented method of Rodd. The difficulty of separating zirconia from baddelyite and other ores and obtaining a pure sample was exceptionally great. He had devised a method quite different from that of the National Physical Laboratory in which ore was opened up by means of hydrofluoric acid; the extraction was carried out on an industrial scale, and he obtained zirconia which was dead white. He was interested in the quantitative separation of titanium from zirconia, and would welcome

information on this point. Experiments showed that the presence of iron, alumina, titanium, etc., did not interfere with the quantitative determination of zirconia, if the latter was determined by means of "cupferron" as elaborated by Thornton and Haydon.

Mr. F. H. ALCOCK suggested that an effective method for opening up refractory ore was by fusing with calcium oxide or with potassium hydrogen sulphate.

The CHAIRMAN suggested the opening up by fusion with acid sulphates as leading to a possible simple analytical method when insoluble sulphates were involved. In dealing with rich lead alloys, especially those containing a few per cent. of antimony, he had found direct fusion with potassium acid sulphate and subsequent treatment of the melt with water a rapid means of obtaining the insoluble sulphate, and, indirectly, especially convenient for the titration of antimony in the filtrate.

Mr. ROSSITER, in reply, said the process was very similar to that described by Rodd, the chief difference being in the use of sulphurous acid. Rodd, in his paper, pointed out that the precipitation of the basic sulphate depended upon the previous history of the solution of zirconia, but the previous history of his solution was not given. A very complete account of analytical methods for opening up and analysing zirconia ores had been given by Lundell and Knowles (J. Amer. Chem. Soc., 1920, 42, 1439). The separation of zirconium from titanium was not complete by the method described. Sodium salts were used in preference to potassium salts in opening up the ore because zirconia formed difficultly soluble salts with potassium salts. The solution obtained by fusing the ore with acid sodium sulphate and lixiviating the product would on boiling give a basic zirconium sulphate precipitate, providing it was nearly neutral, but this precipitate would most probably be difficult to filter and wash, it would not settle, and would not be free from iron. It was difficult to obtain anything like a quantitative separation of zirconia as basic sulphate from an acid solution; that was the reason why, after the ore had been opened up by caustic soda and the part insoluble in water extracted with hydrochloric acid, it was necessary to evaporate the excess of acid completely before dissolving in water. Without doing this it was impossible to effect a good precipitation of the basic sulphate.

MR. JOHN ALLAN IN THE CHAIR.

THE ORIGIN, DEVELOPMENT, AND VALUE OF THE THALLEIOQUIN REACTION.

BY WM. BEAMONT HART, F.I.C.

(*Abstract.*)

An investigation as to the analytical value of the thalleioquin reaction was carried out by the author in the year 1909, but the results as to its quantitative value were of such a negative character that they were not considered to be worthy of publication at the time; in view, however, of later published work, they appear to have some importance.

The earliest published record of the green coloration produced by the addition to a quinine solution of chlorine water followed by ammonia is made by H. A. Meeson (Phil. Mag., 1835, 158), who gave its sensibility as 1 in 8750. In Merck's "Reagentzien Verzeichnis" Manson's reaction for morphine and quinine is mentioned, but from the description and references it is quite evident that the name "Manson" is a misprint for "Meeson." Brandes and Leber, 1839, gave the name of dalleiochin or thalleioquin to the green product, hence the name of the reaction.

The reaction has been developed in various ways too numerous to detail here, by substitution of bromine for chlorine or by different methods of liberating halogen, to a sensitiveness of 1:20,000.[1]

Attempts have been made to use this reaction for the colorimetric determination of quinine, using varying quantities of halogen per quinine molecule: Trimble[2] used 38 atoms of chlorine; Léger[3] used 13 atoms of bromine, and states that the method is useless; Vondraseck,[4] using potassium bromate and hydrochloric acid, assumed that with modification and practice it could be used; La Wall used from 10 to 40 atoms of bromine from potassium bromate and hydrobromic acid per mol. of quinine.[5]

From the figures given by Trimble and Léger—the only data found up to 1909—it appeared that the amount of halogen used was excessive and variable. The present author therefore investigated the reaction to determine more minutely (1) the exact conditions necessary, (2) its limit of sensitiveness, and (3) if it were possible to base a quantitative method on it, using bromine as the halogen.

The following solutions were used: (1) Quinine as sulphate, at dilutions 1:1000 to 1:200,000; (2) bromine water, freshly made; and (3) ammonia, 5% solution. Preliminary trials showed that the shade of colour produced depended on (1) the quantity of bromine, (2) time of action of bromine before addition of ammonia, and (3) deterioration of colour by standing after reaction is obtained.

Quantity of bromine.—In all, eleven dilutions were treated with increasing amounts of bromine, starting with 0·75 and increasing by 0·75 up to 12·75 atoms per mol. of quinine, ammonia being added after similar times of action, the solutions made up to a total volume of 25 c.c., or 2¼ inches in the tube, and the colour shade noted, with the following results:—

With quinine solutions 1:1750 or stronger, and with 6 or more atoms of bromine per mol. of quinine, before ammonia addition, a yellow precipitate is obtained.

With increase of bromine and addition of ammonia the colour proceeds from blue, blue-green to yellow-green and yellow; finally this yellow disappears, except in solutions 1:5000 or stronger.

The strongest colour depth is obtained with 6 atoms of bromine shown consecutively in dilutions 1:1750 to 1:1,200,000; at 1:1000 this maximum appears somewhat earlier with 5·25 atoms of bromine, but the difficulty of comparing colours of precipitates may account for this.

The stronger the quinine solution, the earlier does the yellow shade of green appear; at 1:1000 to 1:10,000 it appears before and extends longer in the series after the maximum colour is attained.

Contrary to a published statement[3] that no green precipitate is obtained in quinine solutions of greater dilution than 1:1000, these results show at 1:5000, with 6 atoms of bromine, a decided cloudiness; at 1:2500, with the same amount of bromine, a precipitate; at 1:1750 this precipitation begins at 0·75 atom, is distinct at 2·25 atoms, and increases up to the addition of 6 atoms of bromine.

During the addition of ammonia, at dilutions of 1:1000 to 1:5000, a pink coloration is first obtained, which appears earlier with increase of

quinine concentration; in every case, when the solution is alkaline, this coloration changes to green on standing.

With increase of bromine, at dilutions of 1:1000 to 1:5000, during addition of ammonia, white fumes appear, which with increase of quinine appear earlier in the series; these fumes were noted with bromine present to the extent of about 0·023 g. per 100 c.c. of solution in excess of the 6 atoms per quinine molecule.

Time of action of bromine before addition of ammonia.—Experiments were now made to find the influence of definite intervals of time of action of bromine before addition of ammonia, the intervals chosen being immediate (five seconds), one minute, and five minutes, with the following results: With immediate action, and addition of ammonia till the solution is alkaline, the best results are obtained with stronger solutions, down to 1:40,000, according to the amount of bromine present; with one-minute action weaker solutions give the best results; action of bromine for five minutes reduces the resultant colour strength, but in the weaker solutions (1:40,000 downwards) this is still of deeper shade than with the corresponding dilutions with immediate action.

Colour-strength deterioration.—Trials made for this purpose showed that the green colour fades to some extent, but not very materially up to five minutes.

The following conclusions are drawn from the above results: (1) Excess of bromine and its prolonged action are detrimental to the production of the thalleioquin reaction, 6 atoms of this halogen for one minute being ample for strongest colour depth; (2) with quinine solution 1:1000 to 1:20,000 the reaction commences in presence of 0·75, at 1:40,000 to 1:80,000 in presence of 1·5 to 2·25, at 1:120,000 in presence of 3, and at 1:200,000 in presence of 6 atoms of bromine per mol. of quinine; (3) as a qualitative reaction, by making a few preliminary trials it can be made very sensitive, the limit being 1:250,000 in a depth of liquid 2½ inches (of course, the greater the depth the greater will be its sensibility); for quantitative work, with so many variables, no credence of even approximate accuracy can be assigned to the reaction, except under very strict conditions and in very dilute solutions, as shown.

Bromine absorption in aqueous solution.—Attempts were made to determine the bromine absorption of quinine in aqueous solution for 5, 10, and 20 minutes' action with 2·5, 5, and 11·5 atoms of bromine per mol. of quinine, using quinine at 1:1000 and bromine water at one-tenth saturation, the excess of bromine being titrated with thiosulphate after addition of potassium iodide. The results obtained showed that although four atoms of bromine appears to be the maximum quantity absorbed, and this is constant for five minutes, yet any excess over two atoms is only loosely held and appears to be slowly given up again.

The earlier workers (Andre, Brandes, etc.) did not find chlorine in their product; Commanducci,[6] by varying the time of action of chlorine, obtained two new red products even in alkaline solution—a statement at variance with the present author's bromine results. Comstock and Koenigs,[7] by extracting their quinine dibromide with water and separating by means of ammonia, did not obtain any thalleioquin reaction. Buraczewski and Dziurzynski,[8] on treating their quinine pentabromide with water not above 40° C., filtering and adding ammonia to the filtrate, obtained a white flocculent precipitate which soon became emerald-green and contained bromine, and they state that it is probably identical with the substance formed in the thalleioquin reaction. Christensen,[9] by progressive chlorination of quinine, obtained (1) quinine hydroxychloride and dichloride, in which the vinyl group is saturated and which give the thalleioquin reaction when chlorine followed by ammonia is added to the slightly acid solution; (2) with 4 atoms of chlorine, an unstable base, 5-chloro-6-hydroxycinchonine hydroxychloride, which gives the thalleioquin reaction on treatment with an oxidising agent, a substance that combines with chlorine, and ammonia; (3) with 6 atoms of chlorine, an unstable base, 5-dichloro-6-ketocinchonine hydroxychloride, which liberates two atoms of iodine from potassium iodide for the one active chlorine present and therefore probably contains the group —CO.CCl$_2$— in the quinoline nucleus, with consequent conversion into the group —C(OH):CCl—. This base gives the thalleioquin reaction on addition of ammonia only; the green product on drying leaves a residue of chloro-5.6-diketohydroxycinchonine, the group —CO.CCl$_2$— being replaced, in presence of ammonia, by the —CO·CO— group.

As far as is known, then, the action of chlorine or bromine on quinine in dilute aqueous acidified solution is similar, and the products, beyond the dihalogen stage, that can be formed during or can give rise to the thalleioquin reaction, are numerous. The author attacked the problem from the analytical standpoint, and his conclusion, in 1909, that 6 atoms of halogen are required for the full reaction, is confirmed by the later results of Christensen; these also explain why, in the results of the bromine absorption in aqueous solution, apparently not more than four atoms as a maximum are absorbed, whilst actually six atoms take part in the reaction, the two atoms of iodine set free being determined as unabsorbed bromine. It follows, then, that quinine may be determined from its bromine absorption for five minutes in the manner stated: 1 c.c. $N/10$ Br=0·0081 g. quinine.

It is possible and probable that the progressive halogen action runs concurrently to some extent; that is to say, part of the halogen is preferably used in further conversion of the intermediate products than in full conversion of quinine into intermediate products; this would explain why the thalleioquin reaction is obtained, though not to the full extent, by the action of much less than six atoms of bromine per mol. of quinine. Christensen's statement that the intermediate product, 5-chloro-6-hydroxycinchonine hydroxychloride, gives the reaction by treatment with an oxidising agent, a substance that combines with chlorine, and ammonia, may explain the mechanism of the delay in the final green colour production by Vogel's reaction (1850) and also by Battandier's reaction (1904), since we have the three essentials, time only being necessary; to some extent this also applies to Kletzinsky's reaction (1854), though in this case a further change probably occurs. During the early stage of this investigation the use of a solvent, such as amyl alcohol, for the green product suggested itself, but from the above results it was not thought to be of any value.

Discussion.

The Author, replying to a question, said that it was not practicable to estimate the colour depths by the absorption spectra or by the colorimeter, owing to the rapid changes of colour of the solutions and the large number of experiments being carried out at the same time.

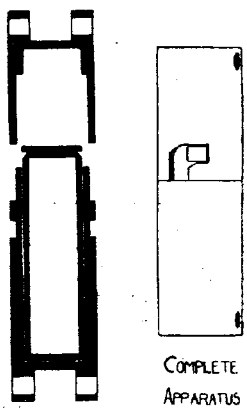
NOTE ON AN APPARATUS FOR SODIUM PEROXIDE FUSIONS.

BY H. J. HODSMAN, M.B.E., M.SC., F.I.C.

The method of fusion with sodium peroxide for converting insoluble combustible matter into a form suitable for ordinary analytical operations is finding many applications, *viz.*, in the determination of sulphur, chlorine, and phosphorus. The forms of apparatus described hitherto have not been free from objection and even risk in handling, especially to the novice, for the reaction is mildly explosive. In some methods the risk is increased by immersing the apparatus more or less completely in water. Screwed threads are liable to seize, making the apparatus difficult to open. The trouble is accentuated if any of the melt solidifies in the threads. Firing by means of heated wires or pellets is erratic, especially to the inexperienced.



The apparatus described below has been designed to avoid these shortcomings. The reaction vessel consists of a thin-walled cartridge of steel tube with a well-fitting cap, having so small a surface of contact that a joint cemented by solidified melt can readily be broken or freed by solution in water. This cartridge is enclosed in an outer cylinder, the lid of which is held in place by a bayonet catch which, when drawn up, holds the cap of the inner tube in place. The cartridge is charged and placed in the outer case, the lid is fitted on, and the apparatus is supported inclined in a clamp and heated at the base for a few minutes over a Bunsen flame until firing has occurred. Alternatively, the apparatus may be placed in a muffle. After cooling, the lid is removed, the cartridge withdrawn, its contents are extracted with water, and the analysis can be proceeded with by the methods in vogue for the determination in question. The outer tube and cover are extended at both ends and bored for the insertion of a rod which facilitates opening. This is unnecessary when the apparatus is properly used. The apparatus can be opened while hot if desired.

Fuel Department, Leeds University.

DISCUSSION.

Mr. W. McD. MACKEY said that when using sodium peroxide in a Roland Wild calorimeter very high results had been obtained in a number of cases, which he attributed to the possible presence of free sodium in the peroxide.

Mr. D. MCCANDLISH asked if the peroxide fusion method could be used for the determination of arsenic in fuels, and also whether the author prescribed any special degree of fineness for the powdered fuel.

The AUTHOR, in reply, said that he had not come across any sodium peroxide which contained free sodium, and he suggested that Mr. Mackey's high results might have been due to leakage of water into the crucible. The peroxide fusion method was especially useful for the estimation of sulphur in coal, but there was no apparent objection to using it for arsenic determinations. He had used it for the estimation of phosphorus in coke. As regards the fineness of the coal powder no special precautions were needed if the powder and peroxide were well mixed. The fact that the whole apparatus was directly heated in a Bunsen burner made it unnecessary to have such an intimate and homogeneous mixture as was required in a sodium peroxide calorimeter. In the author's experience the peroxide calorimeters of Parr gave fairly satisfactory results for the ordinary grades of coal.

Communication.

THE HYDROLYTIC ALKALINITY OF PURE AND COMMERCIAL SOAPS.

(*See* J., Feb. 28, 1921, 27—29 T.)

Mr. R. G. SARAIYA writes as follows:—On p. 29 T, under "Sodium carbonate," it is said:—"Simmons states that 'sodium carbonate has an irritating effect . . . and must only be present to a very small extent in a toilet soap, usually not exceeding 0·15%.' The experiment gave a concentration of hydroxyl ion in 0·15% sodium carbonate *solution* at 25°, amounting to 0·0010 *N*. . . . Thus a maximum alkalinity recognised as permissible is about 0·001—0·002*N* OH′ . . ." Now, Simmons refers to 0·15% of sodium carbonate on the *soap*. The determination of the hydroxyl concentration in the above experiment was made on a 0·15% solution of sodium carbonate. Hence it seems scarcely justifiable to conclude from this experiment that "a maximum alkalinity recognised as permissible is 0·001—0·002*N* OH′." It would be interesting in this connexion to find the OH′ concentration in aqueous solution of a pure soap containing 0·15% (on the soap) of sodium carbonate."

Mr. T. R. BOLAM writes in reply:—"We are indebted to Mr. Saraiya for having pointed out the obvious slip in the short final paragraph dealing with sodium carbonate, which fortunately leaves the experimental data and the paper itself otherwise unaffected. 0·15% sodium carbonate in a soap in the usual technical units amounts to about 1·6% of excess of alkali in the form of carbonate when expressed in chemical equivalents. The data show that sodium carbonate taken alone is much more hydrolysed than an equivalent quantity of soap. Previous data show that in *N*/20 or *N*/10 sodium palmitate solutions the alkalinity is 0·0011 to 0·0014 *N* OH′, and that when to these solutions there is added 1 or 2% (in equivalents) of sodium hydroxide the concentration of hydroxyl ion is increased by about half the normality of the excess of alkali added. This would indicate that addition of even these small quantities of sodium carbonate would increase the hydroxyl concentration of 1% soap solutions by an appreciable fraction."

DR. D. S. JERDAN IN THE CHAIR.

INVESTIGATIONS ON THE RANCIDITY OF BUTTER AND MARGARINE FATS.

BY W. N. STOKOE, B.SC., A.I.C.

Of all the problems which those concerned with the manufacture of fatty foods have to face the question of the occurrence of rancidity, either in the raw materials or the finished article, is probably the most acute. During the warm summer months in particular the manufacturer is constantly haunted by the possibility of his goods going wrong within a short time, in spite of meticulous care during manufacture, and each year an astonishingly large quantity of unsaleable goods finds its way eventually to the soapmaker. It is, therefore, of paramount importance that this problem should be carefully studied, and a thorough insight gained into the conditions causing and favouring the occurrence of rancidity.

A considerable amount of work has already been done and published on this subject, but even yet the nature of the chemical changes covered by the term rancidity is but little understood, and on many points there is still considerable diversity of opinion.

The rancidity of pure fats is now generally understood to be due to a product of hydrolysis and oxidation, and it is usually characterised by the loss of the natural sweetness and flavour of the fat, the formation of compounds of unpleasant odour and taste and a development of acidity in the fat. However, the acidity of a fat is in no way a measure of its rancidity or non-rancidity, for it is possible to have examples of fats showing extremely low acidity and yet being very rancid, whereas other cases may occur in which the fats show a much higher free fatty acid content and yet are perfectly sweet and non-rancid.

In commercial oils and fats the chief causes influencing rancidity seem to be the action of moisture, air, and light, assisted by traces of lipolytic enzymes which may be present in the oils. Generally speaking vegetable oils and fats are free from these enzymes owing to the comparatively high temperature to which the oil is subjected during refining. It is a fact, though, that under certain conditions lipolytic enzymes can withstand a considerably higher temperature than the usual thermal destruction point of enzymes without being destroyed.

Animal fats, on the other hand, being rendered at a low temperature, contain traces of enzymes derived from the tissues of the animal. The presence of enzymes will largely depend on the care taken to ensure separation of tissue.

The first stage in the development of rancidity is hydrolysis, which, however, may be very slight and scarcely capable of detection by chemical means; then oxidation and a multitude of other reactions take place. Some observers state that the oxidation of the glycerol set free in the initial hydrolysis is the actual cause of the rancid taste.

It has been thought that micro-organisms are the cause of rancidity, but in pure fats this is not the case, for organisms introduced into the fat quickly die. In butter and margarine the case is different, for here there is adequate nidus for the development of the organism. Ritsert* found that pure lard was not turned rancid by bacteria, aërobic or anaërobic, and this result has been confirmed by other workers. Duclaux* showed that micro-organisms play no part in the production of rancidity, for the fats being insoluble in water cannot afford nutriment to the cells. The present author's experiments have confirmed this view, though it would appear that a slight hydrolysis does occur in the case of the fat-splitting organisms.

A culture was taken from a sample of rancid margarine showing a free fatty acid content of 1·84%, and the principal organisms present plated out and obtained in the pure culture state. Samples of pure fats were procured and inoculated with the pure cultures. In these experiments the organisms used were a mould, *Penicillium glaucum*, and a bacillus, *B. fluor. non-liq.* After a week the free fatty acid was determined in a portion of the inoculated fats, the remainder being replaced in the incubator. After a second week the acidity was again determined.

TABLE 1.

Inoculated with Penicillium glaucum.

Oil or fat.	Free fatty acid.	After 1 week.	After 2 weeks.
	%	%	%
(*a*) Coconut	0·078	0·085	0·085
(*b*) Palm kernel ..	0·078	0·085	0·085
(*c*) Lard	0·20	0·22	0·23
(*d*) Oleo	0·25	0·26	0·26
(*e*) Prem. jus	0·16	0·19	0·19
(*f*) Groundnut	0·28	0·28	0·29
(*g*) Soya bean	0·19	0·19	0·19
Control 1—Coconut ..	0·078	0·078	0·078
Control 2—Oleo ..	0·34	0·34	0·36

Note.—The free fatty acid is expressed in terms of oleic acid. In all cases the odour and taste were unimpaired.

Table 1 shows the free fatty acid determinations on the fats inoculated with *Penicillium* and two uninoculated controls. The figures for the fats inoculated with *B. fluor. non-liq.* are similar. The results show a slight increase in acidity, whereas there is no appreciable increase in the control samples. As far as taste and odour were concerned the fats had apparently not deteriorated in any way. The fat remaining after the second series of determinations was emulsified with nutrient media and placed in the incubator. In each case after a few days a growth of the mould organism was obtained, showing that the spores of the mould remained fertile in the oil. This point will be referred to again later.

It appears probable that the vegetative cells live for a short time in the fat while the organism uses up its reserve material. In this period the organism presumably secretes a small quantity of lipase which is able to cause a slight hydrolysis of the fat. It is, of course, well known that with enzyme-secreting organisms the maximum amount of enzyme present in the plant is obtained when the plant begins to utilise its reserve material. It is then that the enzyme is best able to diffuse from the cells of the plant.

The rancidity of butter and margarine is almost wholly caused by the action of micro-organisms, which find in these substances a suitable medium for their growth and propagation. To a certain extent the development is restrained by the use of preservatives such as salt and boron compounds, but at best these are but feeble antiseptics in the quantity usually found or allowed in foodstuffs.

The kinds or forms of rancidity which occur are several and may be classified into divisions depending largely on macroscopic appearance, odour, and taste.

* Inaug. Dissert., Berlin, 1890.

* Ann. Inst. Pasteur, 1887; Comptes rend., 102, 1077.

(1) *The fat having a stale greasy taste and odour, but not discoloured or visibly affected in any way.* Instances of this type of rancidity are found principally with pastry margarines, *i.e.*, margarines of a hard nature containing mostly fats of high m.p. These are, as often as not, churned with water only, not milk. This case is comparatively simple, and is really analogous to the rancidity of a pure fat, where the rancidity changes are due to air, light, and moisture, possibly assisted or accelerated by the action of traces of lipolytic enzymes present in the fats. The author has attempted to determine whether or not fats rancidify more quickly than the same fats previously heated to a temperature sufficient to destroy any enzyme present. These experiments were, however, unsatisfactory, and although a good many figures were obtained it would be unwise to attempt to draw any conclusions from them. Generally speaking heated oils increased in free fatty acid content more rapidly than the unheated oils, so that enzyme action is altogether out of the question as far as these experiments go. Of course pastry margarines which contain, as a rule, a major proportion of premier jus or stearine, require to be churned at a high temperature approaching the thermal destruction point of enzymes, and it would therefore be expected that any enzyme present would be considerably weakened, if not totally destroyed. In general the flavour of animal oils and fats is impaired by heat.

Samples of margarine rancid in the form just referred to were invariably old and in most cases had been unduly exposed to air and warmth. The fat had a stale taste and tallowy odour, but did not show an abnormal acidity on analysis. The outside of the margarine was much more affected than the inside.

The "tallowiness" of old butter is another instance of this form of rancidity, seeing that it is not caused by biological conditions, but by the action of air and light.

It seems that this characteristic tallowiness of rancid fats and rancid butter is an oxidation effect. Hunziker and Hosman* suggest that glycollic acid is formed from the glycerol produced by the initial hydrolysis and that the glycollic acid then combines with fatty acids, so producing the unpleasant flavoured compounds. The presence of lactose intensifies the oxidation effect since it leads to excess of glycollic acid. Light does not appear to be essential to the oxidation but has an accelerating effect. Oxidation is accompanied by a decrease in the iodine value.

(2) *The "perfume" form of rancidity.* For want of a better description this form of rancidity, ocurring frequently in margarine, may be termed the "perfume" rancidity. A strong distinctive aromatic odour is produced which is not at all offensive, but the rancid fat has a vile pungent taste.

This form of rancidity is most obnoxious, for it can occur in margarines only a few days old. The margarine may appear perfectly good and wholesome and yet have this most objectionable taste and powerful odour. In more advanced stages of this rancidity the margarine is often discoloured and patchy, but it is usually the early stages with which one has to deal.

In the investigation of this problem a number of rancid samples were procured and biological cultures prepared from each, after which the principal organisms present were isolated in the pure culture state. At this point one fact became evident, namely, that in every case mould organisms, principally *Penicillium* species, were present. Another noticeable feature is the fewness of the lactic acid organisms present on the plates.

* J. Dairy Sci., 1917, 1, 320.

Analysis of the fat of the samples showed that in every case in which this type of rancidity was observed the fat contained a proportion of coconut oil, palm kernel oil, or both. This directly confirmed manufacturing experience, which always associated coconut oil with and blamed it for this trouble.

It was next decided to prepare media containing pure oils and to inoculate tubes of the special media with the organisms isolated in the former work. The media were prepared by emulsifying nutrient lactose, gelatin, and agar with sterilised fats, and in this way media were made up containing respectively coconut, palm kernel, and other common fats. Tubes of these media were inoculated with the different organisms previously obtained and incubated at 68° F. Table 2 shows the results obtained.

TABLE 2.

Incubation: 7 days at 68° F.

Organism.	Wild yeast.	*B. acidi lactici.*	*Sarcina lutea.*	*Penicillium glaucum.*
Coconut oil media	No odour	No odour	Putrid odour. Decomposition of nitrogenous matter.	Very strong "perfume" odour.
Palm kernel oil media	No odour	No odour	Do.	Strong "perfume" odour, same as C.N.
Media containing oleo and lard.	Slightly rancid odour.	No odour	Do.	Musty odour.
Media containing cotton seed oil	Very slight odour suggesting staleness	No odour	Do.	Slight musty odour.
Media containing arachis oil.	Do.	No odour	Do.	Do.
Media containing soya bean oil.	Do.	No odour	Do.	Do.

It will be observed that only the coconut and palm kernel media produced the "perfume" in question, and that the organism concerned was *Penicillium*. Later on a sample of babassu fat was examined in the same way, and was found to give a similar result to coconut and palm kernel. These results were confirmed by repetition using samples of oil of various origin. In every case the mould *Penicillium glaucum* was able to produce this "perfume" rancidity with coconut and palm kernel oils. Up to the present *Penicillium glaucum* was the only mould organism experimented with, seeing it was the principal organism found in the samples examined. Subsequently, however, other mould organisms were isolated from rancid butter and margarine. Pure cultures of these were prepared in the usual way.

Table 3 shows the effect of cultivating the various common mould organisms on media containing coconut oil and butter fat.

It appears from this table that species of *Penicillium* and *Aspergillus* alone can produce the "perfume" odour, but that hydrolysis occurs to a greater or less degree in each case.

The "perfume" odour is not produced with butter fat.

It will be noticed that *Oidium lactis* liquefied the media. This, of course, only occurs in the case of acid media.

In a recent paper on this same subject, H. C. Jacobsen,* who has worked along similar lines, states that the ester odour of rancid coconut oil appears only under microbic influence. He finds

* Folien Microbiologien, Deel V., Afl. 2 (Nov., 1918).

further that only the following moulds have this capacity:—*Penicillium glaucum*, *Aspergillus* spec., *Mucor* species, *Clasterosporium* species, *Hormodendron* spec., *Phoma* spec., and *Cladosporium butyri*. *Oidium lactis* does not cause rancidity.

TABLE 3.

Incubation: 7 days at 68° F. Coconut oil (a), f.f.a. 0·07% lauric. Butter fat (b), f.f.a 0·33% oleic.

Organism.	Coconut oil media. Observations.	(a) F.f.a.	Butter fat media. Observations.	(b) F.f.a.
		%		%
Oidium lactis	Cheesy, not unpleasant odour, gelatin liquefied.	13·6	Strong cheesy odour.	10·3
Penicillium glaucum	Strong "perfume" odour, gelatin liquefied, fat discoloured.	6·1	Slight odour of butyric acid, also somewhat mouldy odour.	3·1
Aspergillus glaucum	Strong "perfume" odour, gelatin liquefied.	6·8	Rancid odour, somewhat masked by smell of mould.	5·2
Botrytis cinerea.	Musty earthy odour, gelatin not liquefied.	4·7	Odour very slight, not distinctive.	4·8
Cladosporium oidium	No appreciable odour, gelatin not liquefied, fat discoloured; black.	2·0	Slightly stale odour, fat much discoloured.	6·5
Mucor mucedo	Earthy odour, gelatin not liquefied.	9·6	Stale odour of rancid butter.	6·8

Fatty acid expressed as (*a*) lauric acid, (*b*) oleic acid.

Jacobsen does not state the precise organism used in his experiments. Certainly *Botrytis cinerea*, *Cladosporium oidium*, and *Mucor mucedo* did not produce the "perfume" form of rancidity.

Experiments were next undertaken to attempt to determine the conditions favouring the production of this "perfume" rancidity.

Influence of the composition of the media.

The following media were prepared, sterilised and emulsified with various oils and fats as before. (*a*) Nutrient broth—peptone, flesh, lactose. (*b*) do., no sugar. (*c*) Nutrient gelatin, no flesh, dextrose. (*d*) Milk. (*e*) Whey soured by pure lactic acid ferment. (*f*) Casein. Portions of these media were inoculated with the pure cultures previously prepared and incubated for a week at 68° F. (20° C.).

Tables showing the individual observations were not drawn up, but briefly the principal points observed were:—

(1) In every instance the growth of species of *Penicillium* or *Aspergillus* upon media containing coconut or palm kernel oils produced the "perfume" form of rancidity.

(2) Of the two oils coconut seems to be the more susceptible; throughout the whole series of observations, as far as could be ascertained, the odour from the coconut media was stronger than from the palm kernel, though identical in character.

(3) The influence of sugar in the media is noteworthy; in absence of sugar the odoriferous substance is not so readily produced.

(4) Mould spores did not readily germinate in the soured whey media, probably owing in some measure to its nitrogen deficiency, but with the casein media there was a prolific mould growth and corresponding rancidity in the course of a few days.

Further experiments were next undertaken to ascertain the effect of acidity or alkalinity of the media. Table 4 shows the relative quantities used and the results of the experiments.

TABLE 4.

Organism: Penicillium glaucum. Media: Coconut oil (f.f.a. 0·07%), gelatin lactose.

Acidity or alkalinity of media.	Observations after 7 days incubation at 68° F. (20° C.).	F.f.a. as lauric acid.
		%
$2\frac{1}{2}$% *N*/10 HCl.	Abundant mould growth; media liquefied, "perfume" odour; fat discoloured green.	4·9
5% *N*/10 HCl.	Less mould growth; media not liquefied; "perfume" odour; discoloration very slight.	2·0
5% *N*/1 HCl.	Much growth of the mould; odour very slight; fat orange coloured.	4·2
5% *N*/10 NaOH	Abundant growth; strong "perfume" odour; gelatin liquefied.	5·4
5% *N*/1 NaOH.	Less luxurious growth; gelatin liquefied; odour very slight.	3·2

The experiments are not very conclusive, but it would appear that the "perfume" is produced even in presence of 5% of *N*/1 acid. In presence of a similar quantity of alkali the perfume is produced to a small extent, but in both cases a considerable hydrolysis of the fat takes place.

The influence of temperature.—This is, of course, very marked. Warmth accelerates the growth of the organism, and for this reason it is really only in summer that the problem of the occurrence of this rancidity is accentuated. In winter the preservatives present in margarine are usually sufficient to restrain undue propagation of the organisms present.

Samples of margarine showing this "perfume" form of rancidity are invariably more rancid at the outside than the inside. As often as not the inside is perfectly sweet and fresh. In more advanced stages the rancidity does penetrate right down through the bulk, but invariably it will be found that the outside is the more decomposed. The free fatty acid content is always found to be much higher at the outside. The "perfume" rancidity is always accompanied by fat splitting to a greater or less degree. This is, of course, to be expected seeing that both *Penicillium* and *Aspergillus* are lipase-secreting organisms. Microscopical examination of the rancid margarine often reveals the presence of mycelia which penetrate through the fat (see Fig. 1).

Thin layer of rancid fat showing disintegrated mycelium of the mould organism. (× 50, unstained.)

FIG. 1.

The mycelia are often much disintegrated and in samples but slightly rancid their presence is sometimes extremely difficult to detect. The amount of the compounds produced giving the strong perfume is exceedingly small. Steam distillation of 200 g. of a rancid margarine only yielded less than 0·1 c.c. of the odoriferous substances.

The question as to the mechanism of the action of this form of rancidity now arises. Apparently air assists the action if not necessary to it. Does lipase so act on coconut and palm kernel oils to produce the effect in question; or is the lipase of the *Penicillium* and *Aspergillus* organisms peculiar to itself; or is another independent enzyme responsible for the acceleration of the change? When coconut or palm kernel oil rancidifies through the usual agency of air, light and moisture the "perfume" is *not* produced; there is produced, on the other hand, the usual stale greasy taste and odour common to rancid fats. Clearly then an additional factor enters into consideration.

In the first instance a solution containing lipase of vegetable origin was prepared from castor oil seeds. Germinating seeds were ground up in a mortar with a 5% sodium chloride solution containing 0·2% potassium cyanide, the whole being allowed to stand after the operation for 24 hours. The filtered solution was then ready for the experiments. Portions of coconut and palm kernel oil were mixed with the enzyme solution, four drops of carbon tetrachloride added, and the test mixtures kept for given periods of time at a temperature of 68° F. In a series of experiments the time, concentration and proportion of enzyme liquid were varied. In all cases hydrolysis of the fat took place to a greater or less extent, sometimes considerable, but there was no production of aroma or "perfume" whatsoever, showing that the lipase alone as prepared from castor seed is incapable of producing the effect in question.

Attempts were next made to prepare the enzyme or enzymes of the mould *Penicillium glaucum*. Several methods were tried without success, but the following method proved fairly satisfactory. A wide vessel was filled to a depth of about ¼ in. with a medium made by emulsifying coconut oil with a gelatin lactose medium. This was liberally sown with spores of the organism and placed in the incubator. After several days a luxurious growth of the mould completely covered the surface of the medium. The latter was then gently warmed to melt it completely and enable the mould plant to be lifted bodily out of the liquid. It was then transferred to a vessel containing distilled water, which was replaced in the incubator. A small amount of the original medium adhered to the plant and was more or less dissolved by the water, forming a substratum for the organism of very low nutritive value. After several days the plant was removed from its watery bed and the liquid filtered several times through cotton wool until free from cellular elements as determined by microscopical examination and incubation tests. Addition of strong alcohol to the solution produced a slight opalescence. Tested with tincture of guaiacum and hydrogen peroxide, a positive reaction was obtained, but the boiled solution failed to give the reaction.

The liquid containing the enzymes was next mixed with sterilised coconut oil in varying quantities with the addition of four drops of carbon tetrachloride, and the tests set aside in the incubator at a temperature of 68° F. A control was also prepared, in which the enzyme liquid had previously been boiled. After a week it was found that the "perfume" odour had been produced and that the fat tasted very rancid, but the control was still sweet to taste, and there was no suggestion of the "perfume" odour. A similar series of tests with the further addition of lactose was made, the results of which confirmed the former. If anything the "perfume" odour was stronger in the last experiments. A similar test with the addition of lactose was made with the castor oil seed lipase solution, but there was no formation of the "perfume" rancidity. Table 5 shows the results obtained, using 10 g. of coconut oil in each case.

TABLE 5.

—	20 c.c.	Present		2·38
—	20 c.c. Boiled.	Present	No odour; taste still quite sweet and fresh.	0·16

It will be observed that the extent of the hydrolysis brought about by the enzyme is roughly proportional to the quantity of enzyme liquid used.

These results appear to indicate that the "perfume" form of rancidity of the coconut group of oils is brought about by an enzyme secreted by certain of the mould organisms acting probably in conjunction with the lipase secreted by the same organism. Up to the present I have not succeeded in preparing this enzyme apart from lipase, nor yet obtained much reliable information concerning its action. It seems, however, to provide a subject for an interesting piece of biological research. Jacobsen in his paper, already referred to, calls the "perfume" produced an "ester odour," and appears to regard it as due to esters of some of the volatile acids. In this he seems to have been mistaken, for although there may be traces of esters present in the substances produced, undoubtedly the greater part is a ketone or mixture of ketones. About 75% is methyl nonyl ketone, and this is accompanied by methyl heptyl and methyl undecyl ketones. By steam distilling a culture of *Penicillium* grown on a medium containing coconut oil a small quantity of these odoriferous substances was obtained in a comparatively pure state. The distillate gave a strongly positive reaction for ketones, but was negative to tests for aldehydes.

3. *Rancidity where there is a marked discoloration of the butter or margarine.*

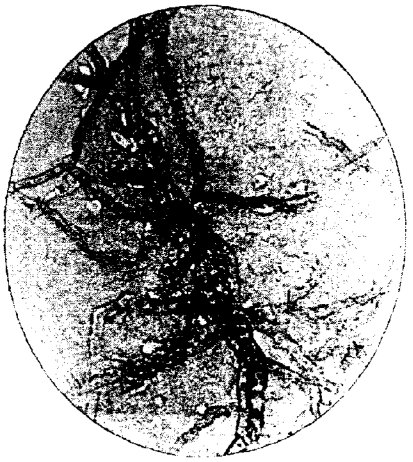
As already indicated, fats in the advanced stages of perfume rancidity often show discoloration. The yellow colour of the fat loses its natural brightness and sometimes the fat tends to lose its colour. Sometimes darker coloured patches are formed. Some time ago dimethylaminoazobenzene was largely used to colour margarine, but of late it has been more or less superseded owing to the action of rancidifying fat upon it. The dye invariably tended to change its shade to a pinkish hue as the formation of free acidity proceeded.

The discoloration of the rancid margarine may take the form of black irregular patches, blue patches, or large spreading pink to red areas dotted over the bulk of the margarine (this must not be confused with the dye effect already mentioned). Sometimes one form predominates, sometimes another, or they may occur together in the same sample.

All these effects are caused by the growth of micro-organisms. In some cases the organisms are

moulds, in others, bacteria or yeasts. By making cultures from the rancid samples showing these effects the responsible organisms were isolated and studied for identification.

The black patches as a rule do not extend to any depth; they are merely surface colonies of the organism. In such cases the rancidity is localised, only the surface layer being affected. The appearance of the fat is repulsive, but the taste is only slightly affected and no odour is produced. The organism causing this trouble is a species of *Cladosporium*, and by smearing the surface of butter or margarine with a culture of the organism the discoloration could be closely imitated. Examination of discoloured portions of the fat under the microscope shows the mycelium of the organism (see Fig. 2).



Discoloured (black) portion of margarine from surface showing mycelium of *Cladosporium*. (× 400, unstained.)

FIG. 2.

Blue-green patches are caused by *Penicillium glaucum* or like species. Here the rancidity is not so localised for the mycelium of the plant seems to be able to penetrate right down into the fat. Considerable hydrolysis takes place and the effect on the coconut group of fats has already been discussed. In absence of these fats usually a mouldy taste and odour predominate. Examination of the fat shows the mycelium of the organism—often very disintegrated. Owing to the disintegration it is usually impossible to identify the organism at this stage. In many cases it is sufficient to place a very small particle of the fat on a microscope slide and press out flat with a cover slip and then examine with a ⅙ in. objective. In less advanced stages of the rancidity it may be necessary, however, to use a larger quantity of the fatty matter and to dissolve away the fat with a solvent. The residue can then be mounted, stained if desired, and examined.

Aspergillus species and other common moulds and fungi produce grey to blue-black discolorations, but these organisms do not occur so frequently in butter or margarine. *Penicillium* species are by far the most common.

The red discoloration is caused by one or two organisms obviously of the chromogenic class as well as by certain wild yeasts. At least three different organisms of this nature, *B. prodigiosus*, *S. rosea*, and *M. roseus*, were isolated and identified in the course of this investigation. These are able to cause hydrolysis of the fat to a considerable degree, but no specially marked deterioration in flavour occurs. There is no odour produced.

There are quite a number of other organisms to be found in rancid butter or margarine. Many of these, if not all, are able to hydrolyse the fat to a greater or less degree. In some cases the deterioration in flavour of the fat is marked, in others the taste is but slightly affected. The following organisms were isolated and identified in the course of the work:—*B. fluorescens liq.* and *non-liq.*, *B. proteus* species, *B. coli*, *B. putrificus*, *Bact. punctatum*, *M. luteus*, *S. lutea*, wild yeasts, and torulas, besides a considerable number of species of micrococci and sarcina which were not positively identified. *Sarcina urea* was found on several occasions. In general the organisms belong to the saprophyte class of bacteria.

In the rancidity changes set up in butter and margarine by these organisms, not only is the action on the fat to be considered; there is further the action on the protein matter of the butter or margarine which may be converted into products conferring an obnoxious flavour and aroma on the sample.

It is now well known that the lactic acid organisms themselves have an effect on the keeping properties of butter. Butter prepared from pasteurised cream keeps better than butter prepared from soured cream, other conditions being equal.

In general it is at present impossible to dogmatise as to the definite chemical changes produced by the organisms either in respect to fat or to protein matter; also it is impossible to catalogue rancidity-producing organisms, and in many cases, owing to insufficient description, it is very difficult to identify organisms found.

Just recently a sample of rancid margarine, purple in colour, was examined, from which moulds of the *Penicillium* species were isolated as well as a large fission fungus so far unidentified.

In butter yeast organisms are often found. The action of these is very interesting and possibly capable of being developed to a useful end. A small amount of fat splitting proceeds, and a medium containing coconut oil increased in acidity from 0·1% to 0·8% in a month when inoculated with the organism. A slight, rather pleasant fruity odour is produced alike in most neutral fats. It seems also that certain acid-resisting yeasts have the property of associating themselves with the lactic acid organisms, whereby the life of the latter is prolonged. This appears to have considerable bearing on the flavour-keeping properties of butter and margarine, and samples prepared using mixed cultures under appropriate conditions remained sweet, fresh, and of good flavour for several months, although kept under usually unfavourable conditions.

These investigations have demonstrated the vital necessity of preventing the contamination and invasion of butter and margarine by undesirable rancidifying organisms. A thorough examination into the possible sources of contamination during manufacture was carried out, and in the course of this work some very interesting facts were revealed.

1. *Contamination from air, utensils, machinery, etc.*—This is very important, but it can be reduced to a negligible quantity by thorough cleanliness in manufacturing processes and by sterilising and disinfecting the air in the factory, all utensils, etc.

2. *Raw materials.*—This is perhaps the most serious question of all. Hitherto raw materials have been judged as regards quality on taste, odour, and chemical analysis. As a result of an exhaustive bacteriological investigation it was found that the usual tests are of little value if the oils are not sterile to begin with, owing to the germination of the spores once the material is manufactured and mixed with nitrogenous matter. In addition to the usual tests, therefore, a bacterio-

logical examination of the raw materials used in margarine manufacture is strongly advocated. During the past two years several hundred samples of commercial oils and fats have been submitted to a bacteriological examination. Of these less than 5% proved to be sterile, some 10—20% contained not more than 6 spores per c.c., but the majority simply teemed with spores of mould, mucor, and other spore-forming organisms. Invariably liquid oils were worst in this respect, and so far not a single perfectly sterile sample has been found. Hardened fats proved to be sterile, or practically so; coconut and palm kernel oils were usually fairly sterile, that is to say contained less than 10 spores per c.c., but nevertheless some very bad samples of these oils were encountered.

Animal fats are fairly sterile, but many samples were found to contain bacteria spores rather than mould spores. The vegetable oils usually contain mould, mucor, and fungi rather than bacteria spores.

The following organisms were found to occur most frequently in the oils and fats:—*Penicillium* species, *Aspergillus* species, *Cladosporium* species, *Botrytis cinerea*, *Mucor* species, and a few common sporulating bacteria.

The most satisfactory method of making a bacteriological test on oils and fats was found to be as follows:—Portions of 1 c.c. and 2 c.c. of the oil or just melted fat are withdrawn from the sample by means of sterilised pipettes and run into tubes of nutrient sugar gelatin, the latter being melted. The mouth of the tube having been "flamed," a sterilised stopper is quickly inserted and the mixture of oil and medium violently shaken to produce an emulsion. This is finally poured out into a cold Petri dish, when it will be found that the emulsion sets before any separation of oil or fat occurs. The Petri dishes are then placed in the incubator at a suitable temperature and examined after two or three days, when a count of the colonies present may be taken.

The question of the origin of the mould spores in the oils and fats naturally arises. It would be expected, naturally, that any spores pre-existing in the crude oil would be destroyed during the deodorising process in which high temperatures are employed. It was thought desirable actually to investigate and check this point, seeing that autoclave conditions do not obtain during deodorising, but rather a vacuum is employed. In carrying out this work the author was indebted to several well-known firms of oil refiners who allowed him to visit their works and draw samples at various stages of the refining and deodorising processes, and in particular to one firm who took an active part in the work. The samples so drawn were tested as described. The investigation yielded some remarkable results, which, briefly, were as follows:—

(*a*) Mould spores existing in the oil prior to deodorising are not invariably destroyed during the process even at a temperature as high as 150°—170° C., the temperature being maintained for several hours. Many spores are destroyed, however, the count being invariably much less after deodorising than before.

(*b*) Mould spores can remain in a fertile condition in oils for a very long time, only awaiting favourable conditions for development and propagation.

(*c*) Where filtration is carried out after deodorising, the oil is liable to infection from air and from the filter cloths.

(*d*) The quality of the seeds or nuts or crude oil has a good deal to do with the relative sterility of the finished oil. With carefully picked seeds or nuts the oil, even before deodorising, is very free from spores so that the deodorised oil has a better chance of being sterile, or approximately so, than in the too frequent case where the seeds or crude oil are of inferior quality. Undoubtedly the quality of the seeds and nuts largely governs the number of spores in the finished oil.

(*e*) The use of wooden barrels or containers is much to be deprecated. It is practically impossible to sterilise the wood, and there is always danger of mould development on the wood if it should become damp and have access to air. Further, the canvas which is put on the bungs of the barrels teems with mould spores (see Fig. 3).

Canvas from bungs of barrels embedded in nutrient solution after germination of spores. (Natural size.)

FIG. 3.

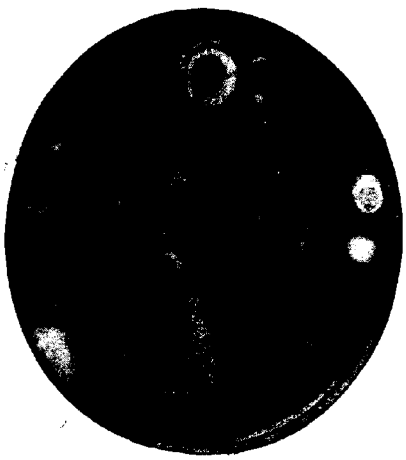
With regard to (*a*) it is difficult to explain the undue resistance of the mould spores to such great heat, and no reference or mention of such a high temperature could be found in the literature. It is to be noted, however, that the oil is heated under dry conditions and under reduced pressure, both factors being usually additive so far as resistance of the spores to heat is concerned.

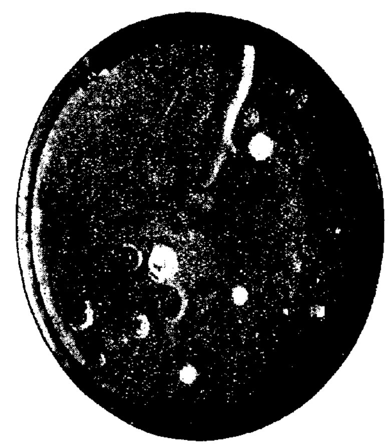
3. Leaving now the question of sterility of oils and fats and the containers, there remain to be considered the parchment paper and wrappers used for the finished margarine or butter. Many tests were made on all kinds and makes of paper, and in not a single instance was the paper found to be sterile, usually much the opposite. Mould spores, chiefly *Penicillium* and *Cladosporium* species, and various bacteria organisms abound. Figs. 4 and 5 show two tests made on different grades of paper. When such paper is used on margarine or butter the necessary dampness and nidus for the propagation of the organism is at once supplied. It is then only a question of time before dark green or black spots (colonies) make their appearance, ruining the butter or margarine as a saleable article.

Throughout the work, lasting nearly two years, the utmost precautions were taken to ensure freedom from contamination, either in drawing the samples or in making the tests; in many cases a sterile chamber was used when the sample required to be opened, even momentarily. One important point resulting from these investigations has had to be omitted for commercial reasons, viz., the ques-

tion of actually preparing a perfectly sterile oil without injuring its flavour or neutrality in any way.

Nothing but the utmost care and bacteriological cleanliness and sterile materials can help the margarine makers to put out a good, regular, butter-like product, which will keep its clean taste for a reasonable time. There is no doubt that failure to realise these conditions is largely responsible, not only for the tendency to rancidify, but for the variations in quality of butter and margarine with which we are so familiar.





Parchment wrappings embedded in nutrient solution, showing colonies grown from the mould spores existing in the paper. (× ½.)

Meeting held at Burlington House on March 7, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

FACTORS INFLUENCING THE NUTRITIVE VALUE OF LARD AND LARD SUBSTITUTES.

BY J. C. DRUMMOND, D.SC., F.I.C.

Until comparatively recently the food value of oils and fats was regarded almost entirely from the calorific standpoint, and accordingly most of the experimental work was devoted to determining what percentage of the total calorific value of each product could be absorbed by the digestive system of the mammalian organism. The discovery of the vitamins* by Hopkins in 1912, and the subsequent differentiation by later workers of three individual substances of this type has, however, led to a very fundamental change in our conceptions of the rôle of fats in the diet.

It has been shown that many naturally occurring fats, particularly those of animal origin, may serve as valuable sources of one of these indispensable, but as yet unidentified, dietary components, the so-called fat-soluble A or vitamin A.

Our earlier researches led us to believe that oils of vegetable origin are practically devoid of this valuable component, whereas the majority of animal oils and fats show its presence. (Earlier literature given by Halliburton and Drummond, J. Physiol., 1917, 51, 235.)

As a result of improvements in the technique for conducting tests for the presence of the vitamin A, this view has been somewhat modified in a recent paper (Drummond and Coward, Bichem. J., 1920, 14, 668), where it is shown that there is no hard and fast line between the vegetable and animal oils and fats when they are regarded from the standpoint of vitamin content, and that there are many factors which may influence the amount of this substance present.

In this paper it was pointed out that the chief factor determining the presence of the vitamin in animal products is the diet which the animal has been receiving. Apparently the vitamin A cannot be synthesised by the animal body, so that only when the diet contains ample supplies of this constituent can appreciable amounts be demonstrated in the tissue fats.

Quite early in the study of the vitamin present in certain edible oils it was observed that lard appeared to be devoid of this important constituent (McCollum and Davis, J. Biol. Chem., 1913, 15, 167), and on many occasions subsequently this observation was confirmed by other investigators.

In a recent summary of the knowledge concerning the vitamins, the author wrote "no entirely satisfactory explanation of the deficiency of lard has yet been advanced" (Special Report No. 38, Medical Research Council. H.M. Stationery Office, 1919). Researches carried out since this statement was made have, however, provided what is regarded as a satisfactory solution to the question.

Before proceeding to describe the investigations on the food value of lard and lard substitutes from the point of view of vitamins, reference may be made to a few experiments which the author made some time ago on the digestibility of these products.

* It is proposed to employ the term "vitamins" for these substances of unknown character rather than "vitamines" proposed by Funk, since the latter word implies, according to the Chemical Society's system of nomenclature, that the substances are of a basic nature. There is no evidence that this is so and they should therefore be classified as substances of unknown constitution (see Drummond, Biochem. J., 1920, 14, 660).

The digestibility of lard and lard substitutes.

The majority of edible oils and fats are well digested and absorbed by the mammalian alimentary tract, and it is very unusual to encounter a low coefficient of digestibility. There is a general opinion that the chief factor governing this coefficient is the melting point of the fats, and to a certain extent this appears to be correct, but it is doubtful whether the question is quite as simple as this. In the author's experiments all the samples of lard and of substitute lards which were investigated gave a high coefficient of digestibility.

TABLE 1.

Sample.	Approx. m.p. °C.	Length of trial. Days.	Average coefficient of digestibility. %
Neutral lard I.	37·5°	10	97·7
" " II.	37°	10	98·2
Hardened cottonseed oil, lard substitute I. ..	40°	7	96·1
Hardened oil, lard substitute II.	38°	10	97·2
Lard substitute A (compound lard)	36°	7	96·4
Lard substitute B (compound lard)	37°	7	96·7
Lard substitute C ..	37°	7	97·5

These results confirm records by other investigators. On the basis of the old theories regarding the food value of fats, therefore, there would be little to choose between any of these products.

The newer knowledge of the vitamin content of oils and fats has taught us how erroneous such a conclusion may be, and accordingly a study of the vitamin content of the lards and lard substitutes was initiated. The technique of conducting these feeding tests is now so much improved that results of a roughly quantitative nature may be obtained provided very great care is taken (see Drummond and Coward, Biochem. J., 1920, 14, 661). This biological method of testing is of course necessary in the absence of any chemical or physical means of estimation.

The vitamin content of lard.

Recent researches have demonstrated that the amount of vitamin A present in the body fat of an animal is determined to a great extent by the diet which the animal has received.

Apparently the animal organism does not possess the power to synthesise this peculiar substance, but can store up a reserve in certain localities such as the body fat when a surplus is provided in the diet. There did not therefore appear to be any reason why the pig should differ from other species in this respect. In collaboration with Capt. J. Golding, D.S.O., of the Research Institute for Dairying, University College, Reading, and Dr. S. S. Zilva, of the Lister Institute, experiments were made to throw light on these points.

At the outset it was evident to us that the usual dietaries on which pigs are raised in this country are in the majority of cases low in vitamin A. It therefore appeared quite feasible to argue that the growth of the pigs might demand most or all of the accessory factor in the diet, leaving little or no surplus for storage in the fatty tissue.

To test this point experimentally batches of young pigs were reared on dietaries some of which were practically devoid of the vitamin A, whilst others supplied ample amounts of that substance. These experiments have been fully described in a previous communication (Drummond, Golding, Zilva, and Coward, Biochem. J., 1920, 14, 742).

Certain animals from each lot were slaughtered after several months on the special diets when they had reached the size of porkers (about 180 lb.), and samples of leaf fat (peri-nephritic fat) and back fat were removed. By means of the biological method these fats were tested for the presence of the vitamin A, and the results proved to be most interesting.

Briefly this method of testing is carried out as follows:—Young animals, usually rats (since many standard data have now been collected for this species), are fed upon an artificial dietary which has been rendered as free from vitamin A as is possible. Upon this diet they are usually able to grow for a short time, presumably whilst they are utilising the reserves present in their own tissues, but after the elapse of a few weeks this growth ceases and the health and weight of the animals decline.

If at this point the diet is supplemented with the foodstuff to be tested the resulting effect on the health and growth of the animal is in the majority of cases dependent on the amount of the vitamin in the added substance. If no vitamin is present the decline of the young animals proceeds to a fatal termination, but on the other hand a recovery of health and a resumption of growth will indicate the presence of the accessory substance A. With the improvements in technique it is now possible to obtain roughly quantitative data by this method, but it is much to be hoped that a chemical or physical method will soon be available so that a much greater degree of accuracy will be attainable.

By this method the samples of fats removed from the various batches of pigs were tested, and it was found that the body fats of swine fed on dietaries supplying ample supplies of the vitamin A contained that substance, but that its presence could not be demonstrated in the fats derived from the animals fed on the foods deficient in vitamin A.

It was therefore apparent to us that the pig resembles other species concerning which data are available in possessing the power to store supplies of the vitamin A in its body fat under suitable conditions.

The next step in the investigation was to ascertain why the majority of samples of lard contain no detectable trace of the accessory constituent. We were fortunate in obtaining the co-operation of Messrs. Harris and Co., of Calne, Wiltshire, at this stage of the work, and must express our appreciation of the very valuable help which they so readily rendered. From material which they placed at our disposal it was possible to show that the average samples of pig fat used in lard manufacture in this country contain small but appreciable amounts of the vitamin A.

The processes of lard manufacture were examined next in order to ascertain whether destruction of the vitamin occurs.

The destruction of the vitamin A at high temperatures was at one time believed to be due to the heating alone (Steenbock, Boutwell and Kent, J. Biol. Chem., 1918, 35, 577; Drummond, Biochem. J., 1919, 13, 81), but more recently it has been shown that temperatures up to 120° C. do not inactivate the vitamin unless there is contact with air or oxygen. It would appear, therefore, that the destruction is probably due to changes of an oxidative nature (Hopkins, Biochem. J., 1920, 14, 725; Drummond, Biochem. J., 1920, 14, 734; Zilva, Biochem. J., 1920, 14, 740).

The older methods of lard manufacture, which still exist in many places, are essentially modifications of the original farmhouse process in which the fat is rendered at low temperature and separated in a simple manner from the connective tissue and water which forms the lower layer of the melted material.

Such a process would not bring about much oxidation, and accordingly it appeared probable that lards prepared in this manner would retain most of the vitamin present in the original fat.

Products of this type are usually termed "butcher's lard" or "home rendered lard."

This we have found to be true by actual experiments. Good recovery curves were shown by animals fed on a sample of pig fat and also on a lard prepared from this fat by a very simple rendering process in which the minced fat was melted in a steam jacketed pan at a temperature of approximately 70° C. The melted fat is stirred very little beyond what is necessary to obtain a satisfactory separation of the layers by adding salt, etc., and the clear, upper layer is merely run off and packed after being subjected to a simple straining or filtration.

Such a product appears to be as rich a source of the vitamin as the original crude fat. Very little lard is prepared by this type of process in Great Britain, but a similar method appears to be used extensively in America for preparing the products known as "Neutral lards Nos. 1 and 2" (Lewkowitsch, 5th Edn., 1914, Vol. 2, p. 689). It is therefore rather surprising that American observers have not frequently encountered samples of lard containing the vitamin. Only quite recently has attention been drawn to such a product by Daniels and Loughlin (J. Biol. Chem., 1920, **42**, 359) in the United States, but they advanced no explanation of their results.

It would seem probable, since these investigators took considerable trouble to check sources of error in their experiments, that they were working with lard prepared by a simple rendering process from pig fat containing comparatively a large quantity of the vitamin.

By far the largest proportion of lard made in this country is prepared by processes which involve a certain amount of aeration at high temperatures. Stirring takes place during the melting, and after the separation of the layers the fat is stirred at a temperature of about 102° C. for some 10—15 minutes to remove moisture. The dry fat is then frequently passed through filter presses before packing.

An active sample of pig fat was found to have lost practically the whole of its vitamin A after being converted into lard by such a process. It therefore appears probable that any technical process involving the contact of the hot fat with air or oxidising agents used for bleaching purposes will considerably lower the nutritive value of the product. The effect of filtration has not been investigated.

Lard substitutes.

(*a*) *Compound lards.*—Two products of this type were examined in an earlier investigation (Halliburton and Drummond, J. Physiol., 1917, **51**, 235) and were found to contain no detectable traces of the vitamin A. Naturally the presence or absence of the vitamin will depend on the nature of the constituent fats.

Both the products investigated were composed mainly of cottonseed oil and oleo-stearin. Experiments on cottonseed oil show that the highly refined edible oil is usually deficient in the vitamin, but nothing is yet known as to the value of the crude oil or of the possible changes which may occur in the vitamin content during the refining processes. These questions are now being systematically studied in collaboration with Dr. Zilva.

Oleo-stearin also appears to be generally deficient in vitamin A. Beef fat normally contains appreciable quantities of this indispensable dietary constituent (Osborne and Mendel, J. Biol. Chem., 1915, **20**, 379), and these observers found on crystallisation of beef fat from alcohol that the vitamin is concentrated in the mother liquors together with the glycerides of lower m.p. This explains why in the process of separating oleo-stearin from premier jus the greater part of the vitamin passes through with the expressed oleo oil. The usual process of oleo oil preparation would hardly be likely to affect the amount of vitamin present.

Considerable variations in the vitamin content of oleo oil may be encountered, but these are in all probability due to the seasonal variations in the diets of the animals. Oleo-stearin is practically always of very low vitamin value. The nutritive value of compound lards will therefore be much influenced by the vitamin content of the constituents employed in its compounding.

(*b*) *Lard substitutes prepared from hardened fats.* In a recent publication it was shown that a sample of whale oil which possessed a fairly high value as a source of the vitamin A was rendered completely inactive by being "hardened" at high temperatures (Halliburton, Paton, Drummond, and others, J. Physiol., 1919, **52**, 325; also Drummond, Biochem. J., 1919, **13**, 81). This was at the time attributed to the high temperature at which hydrogenation was carried out, but this opinion must now be modified in view of the more recent work on the stability of the vitamin to high temperatures in the absence of air or oxidising agents. The cause of the inactivity of the hardened fats from the vitamin standpoint has not been definitely ascertained, but a number of such products, both of animal and vegetable origin, have been examined in this laboratory recently and have shown no trace of the vitamin.

It is therefore not surprising that we have found several samples of lard substitutes prepared on a basis of hardened fats to be devoid of the growth-promoting factor, an experience which has also been encountered by investigators in America (see McCollum, Simmonds, and Pitz, Amer. J. Physiol., 1916, **41**, 361).

Summary.

1. The food value of lard and lard substitutes cannot be estimated solely in terms of digestibility and coefficients of utilisation. Such products are usually well absorbed by the alimentary tract.

2. The nutritive value of lards and lard substitutes may be largely determined by the amount of the so-called vitamin A present.

3. The diet of the pig is the chief factor determining the amount of the vitamin present in the body fat.

4. In the manufacture of lard from a pig fat rich in the vitamin avoidance of aeration or close contact with air or oxidising agents at high temperature will prevent loss of the active substance.

5. Compound lards do not usually contain any appreciable amount of the vitamin A. This is because the constituents most frequently employed (*e.g.*, cottonseed oil, ground nut oil, and oleo-stearin) are almost devoid of that substance.

6. The vitamin content of beef fat is dependent on the diet of the animal. In the manufacture of oleo-stearin from premier jus the vitamin passes through with the lower m.p. fractions into the oleo oil.

7. Samples of hydrogenated fats of animal and vegetable origin were found to be inactive from the standpoint of vitamin A, as also were samples of lard substitutes prepared on a basis of such fats. The cause of the destruction when it occurs has not yet been ascertained.

Discussion.

The Chairman said that the results put forward by the author were of great importance, and tended to show the strong instinct which mankind had for consuming natural fats where possible. Work of this kind showed that there was something more than flavour which determined the desirability of eating butter in preference to margarine and similar artificial products.

Mr. E. R. Bolton said that some twenty years ago it was an achievement to produce absolutely tasteless edible vegetable oils. Then the bacteriologist, by suitable cultures of bacteria, had introduced butter flavour into the fat, and now the biologist showed us that the presence of vitamins was necessary to perfect the oil for food. It would be desirable to find a method whereby the manufacturer could first separate the vitamins from oils, then carry on the refining process, and re-introduce the vitamins which otherwise would be destroyed by the process. It would be interesting to have experimental evidence as to how far the vitamins were destroyed by the process of heating necessary to produce clarification, and whether it was really exposure to oxygen, or heat, or both together, which had the detrimental effect. The process of refining oils in this country necessitated the chemical removal of the free fatty acids, followed by treatment at a very high temperature, but there was little or no exposure to oxygen. If, therefore, vitamins were destroyed in this process the destruction was not, in his opinion, due to oxidation. Olive oils were not usually exposed to high temperatures or to oxidation, and it would be interesting to have a comparison of the vitamin content in edible olive oil and in refined oils.

Dr. G. W. Monier-Williams said that one interesting point was the very high vitamin content of cod-liver oil and whale oils. Terrestrial animals apparently derived their vitamins from vegetable sources. The vitamin content of butter fat was higher in the spring when the cows were grass-fed than in the winter when they were largely stall-fed. From what sources did the whale and the cod obtain their store of vitamin? Presumably it must originate with the marine "plankton," the unicellular organisms which formed the ultimate food material of all marine animals. If so, it would be interesting to trace the course of these vitamins from the organisms in which they were originally formed, through the various marine animals, until they were ultimately deposited in such relatively large amounts in cod-liver and whale oils.

Mr. H. F. E. Hulton asked whether the lard had been given to the rats in the natural state or cooked. If previously fried the vitamin content might be very much reduced, and he thought the rat experiments should therefore be carried out with lard as usually consumed, since, unlike butter, it was not eaten as bought.

Mr. T. Thornley asked if hydrogenation was the only process to which the whale oil had been subjected. It was difficult to hydrogenate whale oil without some previous refining on account of catalyst poisons being present in the whale oil, and it might have happened that some of the refining processes had destroyed the vitamins. He further asked if simple hydrogenation of an unrefined oil at a low temperature had been shown to destroy vitamins, in view of Sekine's work showing that the vitamin content of commercial cod-liver oil, poor in vitamins, was increased by hydrogenation at a low temperature.

Captain Golding said that his share in these experiments had been in the pig-feeding trials. Not only was there a great rise in the curve of growth of the animal when a sow was given cod-liver oil after it had practically ceased to grow on a diet deficient in fat-soluble A, but there was also an improvement in the general well-being of the sow after the change of diet which figures fail to indicate. Crude cod-liver oil was not particularly palatable, but the pigs took it readily. Pigs which had been kept on a diet deficient in fat-soluble A would endeavour to make good the deficiency by eating grass. These observations showed that the question of taste, to which the Chairman had referred, was really a very natural guide, particularly in the animal world.

Mr. A. E. Parkes inquired whether the process of curing pork for conversion into bacon had any effect on the vitamin content.

Dr. Drummond, in reply, said that the refining and deodorisation of oils were part of the investigations now in hand. It was realised that the only way to get reliable information was to take the oils from the starting point and follow them through every stage of manufacture, testing them at each stage. Every such test took some three months to complete, and might necessitate the employment of two or three dozen animals, so that it was a tedious and expensive method. The questions of refining, the removal of the fatty acids, bleaching and filtering through various materials, deodorising, high-pressure steaming, etc., were being worked out. With regard to olive oil, he had not yet made controlled investigations, although in one case he had found evidence of a certain amount of vitamin A in a sample of crude olive oil. His information as regards this oil, however, was scanty. He agreed with Dr. Monier-Williams that it was extraordinary how the cod was able to store such a large amount of vitamins in its liver. The chief types of fish of the white variety—the cod type—appeared to store large quantities of vitamins in the liver, but in the other type of fish, the herring type, the vitamins appeared to accompany the fat distributed in the muscle tissue. He believed that in the case of the cod and the whale, the vitamin was derived primarily from simple marine organisms, and he hoped to go to north Norway, with some colleagues, to find out how the cod obtained its vitamins. It might be that the amount of vitamin produced in marine plants was far higher in proportion than with the ordinary land plant. An eminent marine biologist was accompanying the trip to Norway to throw light on this aspect of the problem. The question of summer and winter butter had been worked out in the preliminary stage, and it had been found that grass-fed cattle in the summer gave milk which possessed a higher vitamin-content than milk from cattle during the winter when the feeding was stall-feeding, such as cake, etc. With regard to the cooking of lard and the experiments on the rats, the experiments were carried out not so much to find out the food value of the fat as consumed, but to settle whether the pig could store vitamin in its fat, and how the vitamin was affected by the technical processes of extraction and refining. Further experiments were in progress. He had tested a sample of crude whale oil before and after hydrogenation. It was possible that the oil had also been refined, but as yet there was no knowledge of the effect of these processes, particularly of the removal of the free fatty acids. Low-temperature work had not yet been carried out. He had not seen the paper referred to by Mr. Thornley, but if the destruction actually occurred by oxidation, it was quite feasible that the vitamin might, perhaps, be restored by a corresponding reduction process.

THE STABILITY OF BENZOYL PEROXIDE.

BY ROBERT CROSBIE FARMER.

Benzoyl peroxide is of industrial interest as an oxidising agent, and has been utilised in several directions under the name of Lucidol. It was introduced by the Verein. Chem. Werke of Charlottenburg as a fixing agent in technical microscopy. It is a powerful antiseptic (Loevenhart, Bull. Comm., 33, 471; Year Book of Pharmacy, 1906, 95), and has been used for the treatment of burns and ulcers. It has a slight anæsthetic action when applied externally. Its internal use has been

given up on account of its poisonous action on the blood (Fränkel, "Die Arzneimittelsynthese"). Its physiological action on dogs was examined by Nencki and Zaleski (Z. physiol. Chem., 1899, 27, 487).

Benzoyl peroxide acts as a drier towards linseed and other drying oils (Krumbhaar, Farben-Zeit., 1913, 18, 1280), and has some application for bleaching oils (G.P. 214,937. See also Utz, Chem. Rev. Fett- und Harz-Ind., 1912, 19, 70, 128, 151; Farben-Zeit., 1912, 17, 2105).

Benzoyl peroxide has a limited application for explosive purposes; since its temperature of explosion is low, its use for electrical detonators acting at low tension has been patented (E.P. 23,450 of 1912).

The compound has generally been assumed to be quite stable for handling and storage. Its behaviour on warming led the author to examine more closely into its stability, and the results given in the present paper indicate that some care should be taken when dealing with dry benzoyl peroxide.

For the preparation of benzoyl peroxide in larger quantities the autoxidation of benzaldehyde does not proceed readily, but the action of sodium peroxide on benzoyl chloride (Nencki and Zaleski, *loc. cit.*) was found satisfactory. The crude product melts at about 98° C., but on crystallisation from alcohol the pure compound of m.p. 103°—104° is readily obtained. It is practically insoluble in water, and almost insoluble in petrol, but dissolves readily in benzene and most organic solvents. It is gradually attacked by warm ammonia, forming benzamide and ammonium benzoate. Sodium hydroxide gradually dissolves it with formation of sodium benzoate.

Very little information has been published regarding the stability of benzoyl peroxide. It is known to decompose vigorously on melting in a capillary tube, and Orndorff and White found that molecular weight determinations at the boiling point of benzene were inaccurate owing to decomposition (Z. physik. Chem., 1893, 12, 68).

Tests made by the author at the Research Department of the Royal Arsenal, Woolwich, are given below by the permission of the Director of Artillery. The stability was measured by means of the velocity of evolution of gas in a vacuum, by the standard method used for testing high explosives, as described by the author (Chem. Soc. Trans., 1920, 117, 1432). The benzoyl peroxide used in these tests was of German origin, and showed the correct melting point for the pure substance. It will be seen that the decomposition proceeds with an acceleration, indicating autocatalysis. For comparison it may be stated that the main high explosives, such as picric acid and trinitrotoluene, show no measurable gas evolution at 100°, whilst tetryl gives only about 0·06 c.c. per g. in 100 hours.

Vacuum stability tests.

(i.) Test at 49° C. Benzoyl peroxide m.p. 103·5°—104° (5 g.) previously dried for 100 hours in a vacuum to remove all volatile matter.

Hours	0	50	100	150	200	250	300
c.c. of gas (corr.) .	0	0·37	0·93	1·37	2·53	3·55	4·63

(ii.) Tests at 80°. Benzoyl peroxide as above (1 g.)

Hours	..	0	5	10	15	20	24
c.c of gas (corr.)	(*a*) ..	0	0·55	1·20	2·10	3·60	6·40
	(*b*) ..	0	0·60	1·35	2·40	4·10	7·45

(iii.) Tests at 100°. Benzoyl peroxide as above. (*a*) 5 g. of peroxide exploded within 30 minutes, breaking the glass apparatus, but without injury to the metal bath. (*b*) 1 g. of peroxide was heated first to 80° in a vacuum and showed a similar rate of decomposition to the above tests at 80°, namely, 0·31 c.c. of gas in 3 hours. The temperature was then raised to 100°, and explosion occurred within 1 hour.

This instability is confirmed by observations on the behaviour of benzoyl peroxide made at this laboratory, which may be summarised as follows:—

Tests at atmospheric pressure.

(i.) When 1 g. of the crude peroxide was heated at 100° a mild explosion occurred after 30 minutes, but the glass tube was not broken. (ii.) One gram of the peroxide, crystallised from alcohol, was heated at 100°. A mild explosion occurred after 1 hour; the glass tube was broken, but the bath was not damaged. Similar explosions were observed on heating pure benzoyl peroxide under water at 100°. (iii.) 7 g. of the crude peroxide was kept at ordinary temperature in a dish in a vacuum-desiccator over sulphuric acid. After 8 hours the peroxide exploded with a sharp noise and destroyed the desiccator. The remains of the peroxide formed a charred mass. (iv.) Slight explosions were observed on grinding dry benzoyl peroxide in a mortar.

The gas evolved on decomposition was carbon dioxide and amounted to approximately one molecule per molecule of benzoyl peroxide. In every case the decomposition was accompanied by an odour similar to that of phenyl benzoate.

Safeguards against explosion.—Wet benzoyl peroxide has shown no explosive tendency at ordinary temperatures, and the manufacture thus appears to be without danger, so long as the compound is not allowed to become dry. In order to prepare a non-explosive dry product, salts were mixed with wet peroxide, and the mixtures dried at 50°. A mixture of 1 part of benzoyl peroxide and 4 parts of sodium chloride decomposed gradually without explosion when heated to 130°. When a flame was applied to a heap of the mixture, the peroxide burned out gradually, but on removing the flame the burning ceased. The benzoyl peroxide can be extracted with benzene from the salt mixture and gives the correct melting point. After keeping the mixture at 45°—50° C. for 20 days, the benzoyl peroxide on extraction still gave approximately the correct melting point. Experiments with ammonium phosphate gave similar results, but the sodium chloride mixture appeared less inflammable of the two.

Summary.—Benzoyl peroxide has explosive properties in the dry state, and drying should be avoided, where possible, in the manufacture. This instability applies both to the crude and the pure compound. The peroxide can be rendered immune against explosion by mixing it in the wet condition with excess of salt and drying the mixture. On warming, the substance decomposes gradually with evolution of gas, and the decomposition is autocatalytically accelerated. Storage of the peroxide under warm conditions is therefore to be avoided.

Hackney.

DISCUSSION.

Dr. H. P. STEVENS asked the author how far purity affected stability. Some time ago he had made some experiments with benzoyl peroxide for vulcanising rubber, but he had not taken any particular care in purifying it. A small quantity had been left standing in a watch glass in a dry, warm place 4 or 5 feet above a gas stove, and it had exploded without being touched. He had mixed benzoyl peroxide with rubber without difficulty by keeping it wet. He wondered whether a carefully purified product would be more stable.

Dr. M. O. FORSTER asked if it exploded when hammered.

Dr. FARMER replied that he had not given it very vigorous hammering. Purity did not, in his experience, affect the stability particularly. He had had the material in a state of great purity, and also in various degrees of impurity, but the time that it would stand heating seemed to be about the same. It did not seem to undergo any increase in stability on purifying. In the case mentioned by Dr. Stevens, possibly the benzoyl peroxide had become very dry by the gradual heating, and so had become more sensitive to heat.

Dr. STEVENS said that in his case the benzoyl peroxide had been mixed on warm rollers heated to 50° or 60° C., and a little spot of benzoyl peroxide had got on this roller and dried, and exploded without any friction.

Newcastle Section.

Meeting held at Middlesbrough on March 7, 1921.

DR. J. H. PATERSON IN THE CHAIR.

THE MANUFACTURE OF ALCOHOL FROM COKE-OVEN GAS.

BY C. F. TIDMAN.

The conversion of the ethylene present in coke-oven gas into alcohol and its derivatives was dealt with by my late chief, Mr. Ernest Bury, at a meeting of the Cleveland Institution of Engineers in December, 1919 (see J., 1920, 94 A). The present paper contains a record of the work that has been carried on during the last twelve months on this subject. The suitability of alcohol as a fuel has already been established, and some figures which will be given in a later part of this paper will indicate how far these claims will hold when the power alcohol has been obtained synthetically from coke-oven gas.

Berthelot (1854) is generally credited with the discovery that ethylene could be fixed as ethylsulphuric acid, which can then be hydrolysed to alcohol, although Henry Hennell indicates in a paper communicated to the Royal Society in 1827 that he had identified sulphonvinic acid in quantity of sulphuric acid given him by Faraday, which had absorbed eighty times its volume of olefiant gas, or, in other words, 5% of its weight of ethylene. In a paper published the following year he states that this sulphovinic acid decomposed into sulphuric acid and alcohol. Fritsche seems to have investigated in 1897, and more thoroughly in 1912, the application of this synthesis to industry, but when he found that 12 cubic metres of scrubbing surface was required per cub. m. of gas treated per minute he decided that the large scrubbing plant necessary would render the proposal unworkable. In the work we have conducted at Skinningrove we have decided that not only surface, but turbulent contact plays a part in deciding the speed with which ethylene will combine with sulphuric acid. While Fritsche seems to have worked along the lines of pressure, we have considered temperature and turbulence to be essential factors in successful and rapid absorption. Since the publication of Mr. Bury's work on this subject, a patent has been taken out by a Belgian firm, where success seems to have been attained by the use of catalysts such as vanadic and tungstic acids.

With very few data at our disposal the problem was attacked at Skinningrove under the direction of Messrs. Bury and Ollander. The first point was to determine the most suitable temperature of absorption, and to this end absorptions were carried out at temperatures 160°—165°, 95°—100°, and 85°—90° C. respectively. The absorption apparatus consisted of two lead pots in series provided with stirring gear and containing 95% R.O.V., through which the coke-oven gas was passed in series. At 85°—90° C. it was found that there was 0·25% of carbon in the acid, showing that even at this temperature decomposition was occurring, while at 160°—165° C. the acid used soon became gelatinous, while the exit gas contained a good deal of sulphur dioxide. Fig. 1 shows the progress of the absorption at temperatures below 85°. The figures for

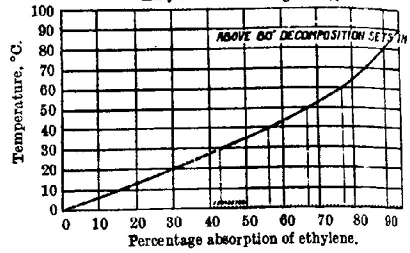

FIG. 1.

Variation of absorption of ethylene with temperature.

these absorptions were obtained by using towers packed with fused silica as absorbers. From these data the best temperature of absorption was considered to be from 60° to 80° C. Four lead towers, each 4 ft. 6 in. by 3 in. diam., jacketed by a cylinder 5 in. diameter, arranged in series, were packed with broken fused silica in such a way that the ratio of free space to packing space was as 2:5. The total capacity of the towers was 1 cb. ft., of which 5/7 cb. ft. represented solid packing material. Sulphuric acid containing 95·4% H_2SO_4 was fed down the towers by means of a siphon and carried to the top at intervals. During the first few experiments acid was fed down the tower continuously in the smallest continuous stream possible (at the rate of about 30 c.c. per minute), but later experiments showed that this was not necessary, since after flushing down the towers the acid flow could be stopped and the absorption continued without appreciable alteration for an hour. In one experiment, for example, the inlet gas contained 1·70% of ethylene; after 5 minutes' absorption the outlet gas was found to contain 0·60% of ethylene. The acid flow was then stopped and the percentages of ethylene in the exit gases were found to be as follows: 10 min., 0·60%; 15 min., 0·64%; 20 min., 0·64%; 60 min., 0·66%. A repeat experiment gave almost identical figures.

In the first absorption experiment carried out, desulphurised gas was passed through a bubbler containing 80% sulphuric acid. The primary object of this scrubber was to remove moisture and any higher homologues of ethylene (propylene, butylene, etc.). In the gas produced under the conditions existing at Skinningrove, however, the presence of the higher homologues has not been observed, although doubtless these exist in small quantities. During the course of an experiment in which a gas richer in ethylene than coke-oven gas was used—viz., gas driven off from beech-wood charcoal, which had been placed in the gas stream—a white, crystalline solid separated out on the 80% acid; this was found to have the empirical formula C_4H_8, m.p. 126° C., b.p. 250°—255° C. With this solid was associated a second solid containing oxygen and of the probable empirical formula C_4H_8O; it had a very characteristic sweet taste, which persisted in the mouth for hours. Even

using ordinary coke-oven gas a certain amount of solids settles out in the preliminary bubblers, but these are easily separated and can be discarded, although further investigation may prove them to be of value.

After the gas had left the scrubber containing 80% acid it was passed through the experimental towers just referred to at the rate of 5—6 cb. ft. per hour, and at the commencement the absorption was as high as 90% of the ethylene entering the system. The experiment was made a continuous one and lasted 145 hours. The average speed of the first 440 cb. ft. of gas was 5·6 cb. ft. per hour, while the average absorption of the ethylene was 90%. The speed of the next 320 cb. ft. was 4·8 cb. ft. per hour, with an average absorption of 65%. The total quantity of acid (95·4% H_2SO_4) used was 3000 c.c. With a gas space in the towers of 2/7 cb. ft. and a gas speed of 5·6 cb. ft. an hour, the time of contact of gas with acid was thus 3·1 minutes, during which 90% of the ethylene present was absorbed. These data multiplied up to plant size, where the daily carbonisation is 800 tons, would suggest the use of nine scrubbing towers, each the size of the ordinary benzol scrubber, *i.e.*, 10 ft. diam. and 80 ft. high. Of these nine towers practically the volume of six would be occupied by packing material, the function of which is to give surface and turbulence. To give surface alone, special packing material was used at Skinningrove in plant experimental towers, but although a large surface was provided, allowing three minutes' contact, 80—90% absorption of the ethylene was not obtained.

Keeping in mind these facts, a series of experiments was carried out in a flask of 1950 c.c. capacity filled with dry desulphurised coke-oven gas. The flask was heated in a water-bath until the temperature of the gas was about 80° C., hot acid (300 c.c.) was added and the flask covered with a non-conducting material and vigorously agitated, to afford adequate surface contact, for periods varying from ½ to 3 minutes. Further experiments were carried out using 5% of silica with the 95·4% sulphuric acid. The results obtained are shown in Fig. 2, from which it is seen that the addi-

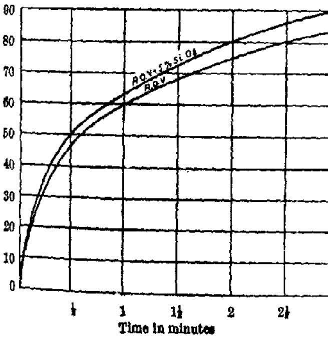

FIG. 2.

Speed of absorption 80° *C.* 95·4 %. H_2SO_4.

tion of silica increases the absorption by approximately 5%. The function of the silica is not quite clear, but it appears to have a catalytic action and not merely a surface effect, since during the first few experiments on the small laboratory towers the absorption was particularly good, while a much later experiment, using the same towers, showed a falling off in percentage absorption, conditions remaining exactly the same except that the silica packing was coated with a slime of lead sulphate. In the experiments just described the addition of silica greatly increased the amount of froth formed on the surface of the acid, this giving much better contact between gas and acid.

From the figures quoted it will be seen that for 3 minutes' contact by either method—towers or direct agitation in flask—the percentage absorption is 90%, so that whichever method of scrubbing is finally adopted—*i.e.*, towers or mechanical washer—it should be possible to remove 70—80% of the ethylene by allowing 2½—3 minutes' contact.

Spraying the acid into the gas has also been tried, but difficulties occurred in maintaining the required temperature and also in the blocking of the sprays. It was decided that this type of scrubber was not suitable. However, certain forms of mechanical washers give practically the spray effect without the disadvantages of blocking of small jets as used in sprays.

The next point to be determined is how nearly sulphuric acid can be saturated with ethylene before it will cease to act as an efficient absorber. Mr. Bury stated that 18% of the acid radicle is available for ethylene absorption, *i.e.*, 95% sulphuric acid (R.O.V.) would continue to absorb ethylene until reduced to 77% H_2SO_4. We have since found, however, that acid already saturated 18% would still continue to absorb ethylene in a mechanical agitator, 30% of the ethylene present being absorbed in 2½ minutes.

A mechanical washer would have the advantage over a tower scrubber system in that the size of the plant would be much reduced, and the power required to drive such washers is not great, considering the power required for pumping and the inconvenience of periodically cleaning a tower scrubber. The absorption product contains free alcohol in addition to sulphuric acid, ethyl hydrogen sulphate, and diethyl sulphate. This was apparent from the results of a trial run on the experimental plant. From analyses of the gases from each scrubber it was seen that No. 1 scrubber gave a shortage when distilled for alcohol, but scrubbers 3 and 4 each yielded more alcohol than was indicated by the gas test. In a number of tests the free alcohol has been as high as 50% of the total yield. It was therefore decided to recover the alcohol by distillation under reduced pressure, first allowing distillation to proceed without steam, and admitting steam when the temperature of distillation increased so that the speed of distillation was maintained. The following figures indicate the procedure. The acid was first diluted to 64% H_2SO_4 by the addition of water. Under a vacuum of 26½ in. distillation commenced at 94° C., the highest temperature recorded being 146°. The alcohol distilled over satisfactorily, and no frothing took place. The finished acid, which was free from alcohol, free or combined, showed 80% H_2SO_4.

The method suggested earlier for recovery of the alcohol was to use a counter-current flow of acid and superheated steam. Over short periods this method was satisfactory, but after a time large amounts of froth were produced which passed into the condensing system.

The bulk of the alcohol obtained from this process is in the form of a 15% distillate, any weaker distillate obtained being used for diluting the acid to the strength required for distillation *in vacuo*. The production of strong alcohol from this weak distillate is hardly within the scope of this paper, since the distillate is of a very similar strength to that obtained by fermentation. The alcohol itself, however, is very interesting in view of the impurities present. These are not important when the alcohol is to be used as fuel, since the alcohol burns completely—indeed, it has been considered possible that the Revenue authorities may even accept the spirit as sufficiently denatured to pass into use without the addition of other substances; certainly the crude spirit is much less potable than

methylated spirit. The alcohol, however, possesses an objectionable odour, which persists in other products made from it. For example, chloroform made from by-product alcohol was reported to satisfy B.P. requirements only after treatment with hot concentrated sulphuric acid to destroy the odorous substances, the washing process reducing the bulk 10%. In preparing strong alcohol from the weak distillate it had been noted that the weak distillate was often cloudy but became clear on heating, showing that the substance present was more soluble in hot than in cold alcohol. Repeated distillations from the 80% alcohol left a residue which on cooling deposited a white, crystalline solid, which was found to be diethylene disulphide (m.p. 111° C., uncorr.). In addition to this impurity a yellow oil containing about 15% of sulphur was found on the surface of the weak distillate. Both forms of impurity were present in largest amount in the first scrubber. Since only a small quantity of the oil is available and it has a wide range of boiling point, it has not been possible to fix definitely the exact substance present. A further difficulty in that diethylene disulphide is very soluble in this oil and consequently it is difficult to obtain the oil free from this substance.

In using an 87% alcohol as fuel without any attempt to remove impurities, quite good results have been obtained in a number of practical trials. In one trial with a 4 h.p. Triumph machine (total weight just over 700 lb.) the following results were obtained:—No. 1 Shell petrol, 64·6 miles per gall.; 50% benzol, 50% alcohol, 78·50 miles; alcohol, 58 miles per gall. A trial with denatured alcohol made from coke-oven gas on a Buick car also gave satisfactory results. The presence of diethylene disulphide appeared to give rise to no bad results.

The diethylene disulphide is derived from the hydrogen sulphide in the coke-oven gas, which contains 6 g. of H_2S per cb. m. The gas for use in the small alcohol plant at Skinningrove is subjected to the ordinary bog iron-ore system of purification. To instal such a system for dealing with 8 million cb. ft. of gas per day is out of the question, since both in capital outlay and labour the cost would be prohibitive. Again, it is very difficult to rid a gas entirely of sulphur compounds by using bog iron-ore purifiers. An alternative method has therefore been devised depending on the well-known reaction between hydrogen sulphide and sulphur dioxide. At first gaseous sulphur dioxide, obtained by the action of acid on sodium bisulphite, was admitted into the gas stream, and the mixture passed up a packed tower. By admitting rather less sulphur dioxide than was theoretically necessary to decompose the hydrogen sulphide it was hoped to precipitate the bulk of the sulphur in the tower, thus producing a gas containing only a small amount of undecomposed hydrogen sulphide which was to be removed by a bog ore purifier. In practice it was found that when the amount of sulphur dioxide present was short of that required very little decomposition took place. The admission of a small quantity of steam gave very little improvement, and passing the mixed gas through hot tubes also failed to remove the sulphur. It was therefore decided to try to desulphurise the gas by the countercurrent system, using sulphur dioxide in solution. This method was found to be quite successful, the gas being easily purified when a large excess of sulphur dioxide was present. The exact excess necessary will no doubt depend largely on the plant itself. Much of the excess of sulphur dioxide is carried forward in the gas stream, but it can easily be removed by scrubbing with water. The sulphur produced in this process is deposited in the form of a mud which can be easily separated from the liquid.

Mr. Bury has pointed out that at a coking plant such as that at Skinningrove, with its 120 Otto regenerative ovens, the make per week, allowing 70% absorption and 70% recovery, would be 9280 gallons of absolute alcohol. When pure gas is used and the alcohol is recovered by distillation under reduced pressure we may easily expect an 80% recovery, while using an acid stronger than 95% R.O.V. we may expect the 70% absorption of the ethylene to be increased. It would not be difficult to obtain, say, 98% H_2SO_4 if instead of erecting a sulphuric acid plant with an acid concentrating plant an oleum plant were installed. The 80% acid left after dealcoholation would form a very good absorbent for the SO_3, while the additional acid thus made would be used for benzol washing etc. The scheme at Skinningrove has been worked out using an acid of 95% H_2SO_4, *i.e.*, R.O.V., but we have noted that an increase of 1 or 2% acidity is of advantage. When using acid of 93% H_2SO_4 we have found that the absorption falls off very rapidly. The figures given by Plant and Sidgwick (J., 1921, 14 T), using concentrated ethylene, show that while 93·1% acid increases in weight 20·8% on absorbing ethylene, 95·8% H_2SO_4 increases 28%. At some point between 95·8% and 98·1% we get a decided increase in the amount of diethyl sulphate formed, while when free sulphuric anhydride is present carbyl sulphate is formed—a substance not hydrolysable by alcohol. When using R.O.V. 95% (approximately) we have not found diethyl sulphate to be formed, although in certain of the crude alcohols produced on the experimental plant traces of the characteristic odour of diethyl sulphate have been noticed. We have also found it advisable to place one or two acid bubblers before the 80% sulphuric acid scrubber to avoid the formation of a substance like pitch, which may easily block the scrubber. When the bubblers are used this tarry product separates out on the surface of the acid and can be removed from time to time. We have not yet determined the composition of this deposit, but in a preliminary examination we have found that it is only partly soluble in water. The soluble portion gives a deep-green solution, and when freed from acid forms a soapy solution giving a persistent film when air is blown through it.

In conclusion, I desire to express my thanks for the sympathetic help and encouragement received from the heads of the Skinningrove Iron Company, Mr. Alfred Hutchison, and Mr. Coulson. I also wish to acknowledge the great help received from Mr. Ralph Robinson, B.Sc., Mr. G. M. Harrison, and Mr. K. L. Brown.

Discussion.

The Chairman suggested the desirability of research into the possibility of using the hydrocarbons of coke-oven gas (which contained a total of 30%) as a source of fuel rather than selecting one small and unimportant constituent for conversion into fuel. The sulphur problem was an extremely serious one having regard to the effect of the sulphur compounds upon the fuel tanks and exhaust apparatus of an engine, and any process devised for the manufacture of power alcohol would have to produce a material practically free from sulphur compounds.

Dr. G. Weyman thought that there should be no great trouble or expense involved in removing hydrogen sulphide, as gasworks were able to make a profit on oxide purification. Gasworks had necessarily to remove every trace of hydrogen sulphide, and there was no trouble in dealing with 10 or 20 million cb. ft. per day. He was not sure if oxide purification plant would not be less expensive than the scrubber system of removing excess of sulphur dioxide which Mr. Tidman had mentioned. In an older process the last trace of sul-

phur dioxide was removed in an alkaline washer. The reaction between sulphur dioxide and hydrogen sulphide was most interesting, but extremely complicated. There were other sulphur compounds besides hydrogen sulphide which might cause the trouble referred to.

Dr. J. T. Dunn suggested that if it were necessary to have the final product free from sulphur, attention would have to be given to the removal not alone of hydrogen sulphide, but of the other sulphur compounds which accompanied it in the gas.

Mr. A. Trobridge said that many years ago he had had considerable experience in separating the last traces of hydrogen sulphide from gas in connexion with the development of the Chance process for the recovery of sulphur from alkali waste. Large quantities of hydrogen sulphide had been passed through the Claus kilns, and it had been necessary to determine the exact proportion of air necessary to give the maximum yield of sulphur; it had been found impossible to obtain an exit gas free from either hydrogen sulphide or sulphur dioxide. The United Alkali Co. had had a similar experience recently at their Gateshead works. He thought that the use of sulphur dioxide for removing the hydrogen sulphide from coke-oven gas did not hold forth much promise, and that some other method should be devised.

Mr. J. E. Christopher said that he had been in touch with a plant in which sulphur was recovered from waste gases, the best yield being obtained when the final gases showed signs of both H_2S and SO_2. If either were present alone the yield was diminished. He foresaw difficulty in introducing alcohol recovery apparatus in many existing coke plants, but the question should be considered more especially in regard to new plants. Had Mr. Tidman any experience of this particular process in dealing with gas from a low-temperature carbonisation scheme? A very high yield of motor spirit would be expected in that case, and if it could be established it would undoubtedly bring low-temperature schemes more into prominence.

Mr. A. Hutchinson said that the paper was really a report of progress in the conversion of a process which had proved a success on a small laboratory scale to a semi-manufacturing scale, with a view to finding the most economical plant for large-scale manufacturing, so as to keep down the capital expenditure to a minimum. So far, the experiments had proved entirely successful, but the number of towers required to complete the extraction of the whole of the ethylene by means of sulphuric acid was so considerable that they were now turning their attention to a small experimental plant designed by Dr. Davidson, which had been successful in ammonia absorption, and, it was hoped, would prove equally so in ethylene absorption. If this proved to be the case, a very considerable saving in capital cost would be effected, and there was every likelihood of the manufacture of alcohol being a paying proposition. He did not think that the sulphur compounds would have any detrimental effect in the use of the alcohol for internal combustion engines, motor cars, etc. Experience at Skinningrove with large gas engines using gas containing a certain amount of sulphur was that the engines were themselves in no way affected by the sulphur. When the waste gases were cooled in water, however, the acid solution affected the exhaust pipes.

Mr. H. Crowe said that at Skinningrove they had run their large gas engines on blast-furnace gas only, which contained only traces of sulphur. They had also for many years run these engines on a mixture of blast-furnace gas and coke-oven gas containing a considerable quantity of sulphur. No ill-effects from the sulphur were felt in the engine until at the point, just past the exhaust valve, where water was injected to cool the exhaust pipes and deaden the noise of the exhaust. From this point onwards, all along the exhaust pipes and silencers, rapid corrosion took place. Large gas engines were more satisfactorily run on pure blast-furnace gas than on a mixture of blast-furnace gas and coke-oven gas.

Major Scott said that he did not think the action of sulphur on the interior of internal combustion engines would be at all serious. He had run gas engines on blast-furnace gas and gas from gas producers and had found no bad results in the cylinders. Corrosion was liable to take place in the exhaust pipes owing to moisture being present.

Mr. Tidman, in reply, said that after removing the diethylene disulphide from a sample of crude alcohol by means of mercuric chloride, the resultant spirit was pronounced by the visiting Excise officer to be equal to grain spirit. His work had all been carried out on gas produced under coking conditions as at Skinningrove, where metallurgical coke was the main product, and had not extended to low-temperature carbonisation. He suggested that such substances as thiophen would be removed in the wash oil of the benzol scrubbers, and so would not trouble the alcohol system. Replying to Mr. Trobridge, Mr. Tidman said that when removing the hydrogen sulphide by means of sulphur dioxide solution in the experimental towers referred to, the gas from the exit of the last tower contained no sulphur dioxide.

GUANIDINE CARBONATE AS A STANDARD ALKALI.

BY A. H. DODD, B.A., A.I.C.

Sodium carbonate is very generally used for the preparation of standard alkali solutions, but it is open to several objections (*cf.* Rimbach, Ber., **26**, 171; Higgins, J., 1900, 958; North and Blakey, J., 1905, 396).

During the last three years guanidine carbonate has been used in this laboratory for making up standard alkali solutions, and has been found to possess certain definite advantages over sodium carbonate. Thus it can easily be freed from inorganic impurities, it contains no water of crystallisation, and, when pure, it is non-hygroscopic.

No reference to its use as a standard reagent has been found in the literature, although Grossmann and Schuck (Chem.-Zeit., **30**, 1205) have suggested its determination by titration with standard acids and recommend it as a powerful alkali to precipitate zinc, etc.

Guanidine carbonate, $[NH{:}C(NH_2)_2]_2.H_2CO_3$, is a strong "mon-acid" base; the hypothetical guanidonium hydroxide from which it is derived approximates in strength to the alkali hydroxides, and is stronger than the tetra-substituted ammonium hydroxides (Ostwald, J. prakt. Chem., (2), **33**, 367). The heat of neutralisation of the free base is 14·12° C. per g.-mol. (Morrell and Bellars, J. Chem. Soc., 1907, 1012).

The carbonate as ordinarily prepared from guanidine thiocyanate, *i.e.*, from ammonium thiocyanate as starting material, is not to be recommended. Generally it is hygroscopic and contaminated with ammonium and potassium salts. In any case the purification is costly, and the yield of

carbonate from thiocyanate, using potassium carbonate and alcohol extraction, is only 70% (Volhard, J. prakt. Chem., (2), 9, 10).

The product made from dicyanodiamide, *i.e.* from calcium cyanamide as raw product, is extraordinarily pure, and should be obtainable for a few shillings a pound.

Guanidine carbonate is precipitated from its aqueous solution by addition of alcohol, and it is best to make use of this fact to obtain the analytical reagent. Two precipitations from its aqueous solution and washing with 80% alcohol yield small white crystals which, after drying at 110° C., show a purity of 100% if tested with standard acids, and can be stored in a well-stoppered bottle and used without further treatment for standard alkali for works use. Samples left covered but exposed to the atmosphere for 14 days in a warm corner of the laboratory did not gain in weight appreciably. Beautiful colourless crystals weighing up to 3 g. can be obtained by slow evaporation from water, but although they are anhydrous they would not, however, be used for analytical work, since they are liable to occlude impurities and a small quantity of water.

Although it is generally admitted that $N/1$ solutions are not sufficiently accurate for analytical work, it is nevertheless the usual practice of acid manufacturers to sell their acids on the acidity of a weighed quantity against $N/1$ caustic soda, itself standardised against $N/1$ acid checked against $N/1$ sodium carbonate.

Accordingly, a $N/1$ solution of guanidine carbonate (90·07 g. per litre) has been compared with $N/1$ sodium carbonate and $N/1$ potassium hydroxide (from mercuric oxide and potassium iodide). The strength of the sulphuric acid was about 0·957 N. The sodium carbonate was Kahlbaum's "pro analysi" dried at 100° C. Solutions were all used at 15° C. in vessels calibrated at that temperature. The following results in g. per l. are the mean of three observations:—

	Sodium carbonate.	Guanidine carbonate.	Potassium hydroxide.
Methyl orange	46·853	.. 46·816	.. 46·91
Congo red	46·67	.. 46·76	.. 47·1
Alizarin red	46·72	.. 46·76	.. 46·78

The acid when standardised against caustic soda itself standardised against $N/1$ hydrochloric acid (by Gay Lussac's method) with phenolphthalein as indicator gave a result of 46·893 g. per litre. These figures show that the testing of sulphuric acid by means of guanidine carbonate instead of sodium carbonate is accurate enough for routine works practice.

Guanidine carbonate has also been used for the standardisation of $N/10$ sulphuric acid. Carbon dioxide was not removed, as is advisable for accurate work. The following table gives the factor of approximately $N/10$ sulphuric acid, each being the mean of three observations:—

Indicator.	Guanidine carbonate.	Sodium carbonate.
Methyl orange	1·0075	.. 1·0081
Alizarin red	1·0049	.. 1·0075
Congo red	1·0060	.. 1·0075

The higher figures with methyl orange are possibly due to a slight acid reaction of the carbon dioxide.

It thus appears that guanidine carbonate should prove a satisfactory and convenient reagent for acidimetry. It merits a more minute investigation, using more delicate indicators, such as bromothymol blue, which are now available.

THE PREPARATION AND PROPERTIES OF 1.3.5-TRINITROBENZENE.

BY L. G. RADCLIFFE AND A. A. POLLITT.

(This J., 1921, 45 T.)

Dr. W. H. Gibson, of York Street Flax Spinning Co., Belfast, wrote as follows:—The evidence produced by the authors for the existence of a less stable form of *s*-trinitrobenzene melting at 61° C. fails to convince me. It appears to me that on the occasions when this material was obtained the conditions were such as to favour incomplete nitration, and the low yields recorded support this view. It not infrequently happens that in the trinitration of benzene a mixture of di- and tri-nitrobenzenes is obtained, which is not easily separated by crystallisation, and which gives a product melting in the neighbourhood of 60° C. It seems possible that Messrs. Radcliffe and Pollitt really obtained this mixture, and the behaviour they observed on preparing the aniline and naphthylamine addition compounds is consistent with this, as they do not state that they obtained a quantitative conversion of the unstable to the stable form through the addition compound, nor do they state that they got equal yields of addition compound from equal weights of the two forms. It may be, then, that only a separation of the 1.3.5-trinitrobenzene in a mixture of di- and tri-nitrobenzenes was effected. The analysis of the unstable form by the Knecht and Hibbert method is stated to correspond with pure trinitrobenzene, but it seems unfortunate that this was not confirmed by a nitrogen determination carried out in the usual manner. Quantitative conversion of one form into the other would, however, be the most convincing proof of the existence of this unstable form.

Mr. Radcliffe replied as follows:—I fear that in condensing the paper certain details have been left out, but we made many experiments involving fractional crystallisation of the product melting at 61° using different solvents, but entirely failed to resolve it or indeed change its melting point; further, we thought at the time that it might be a mixture, and the experiments with aniline etc. and regeneration were done most carefully and with due regard to the quantitative recovery of the trinitrobenzene. I find, from the original notes, that we used several different methods for the determination of nitrogen, and these gave results pointing to the compound being a trinitrobenzene.

Yorkshire Section.

Meeting held at Leeds on November 8, 1920.

DR. L. L. LLOYD IN THE CHAIR.

OCHRE STREAMS OF THE VALLEYS OF THE DON AND LOXLEY.

BY J. HAWORTH AND J. EVANS.

Ochre waters may be defined as natural waters in which salts of iron occur in solution. In most cases such waters deposit iron oxide or ochre on the banks and bed of the stream. They may be conveniently sub-divided as:—(1) Chalybeate waters, which occur either as waters containing carbon dioxide and iron bicarbonate, together with other salts, or as saline acidulous chalybeates containing chiefly sodium sulphate and iron bicarbonate. (2) Waters containing chiefly sulphates of iron.

The chalybeate waters seldom contain large quantities of iron (8 to 15 parts per 100,000). They emanate from strata containing iron in the form of carbonate, which in the presence of carbon dioxide forms the soluble bicarbonate. It is not, however, proposed to deal further with this class of waters, but rather with the second class, which are common in the neighbourhood of Sheffield.

Waters containing sulphates of iron are frequently found in all districts where coal workings exist or where outcrops of the coal measures occur. The streams in valleys draining areas in which coal measures are exposed frequently bear marked indications of the presence of iron salts by the brown and red deposits of ochre on the beds of the streams and by the brown colour of the water.

During the course of certain investigations respecting the water supplies of the city of Sheffield the authors made extensive examinations of the contributory streams to the rivers Loxley and Don. The river Loxley is a tributary of the Don, and the watersheds are divided by a precipitous ridge in which outcrops of the lower coal measures occur at numerous points and are exposed. Beneath the lower coal measures beds of ganister and fireclay occur. These are worked at numerous points on both sides of the ridge, the products being largely used in the Sheffield industries. The mining operations consist usually of driving levels or adits into sides of the valleys at different levels where the outcrops occur, and water drains from these forming streams which flow down to the river. There are also other streams flowing from the slopes of the valley, but a casual observation shows that the streams from the mines or ganister pits all contain salts of iron and deposited ochre, whereas the remaining streams contain no iron.

The physical appearance of the ochre streams is very striking. In some cases the water is clear but coloured, the colour varying from pale yellow to a deep reddish-brown; in other cases the water is turbid through the presence of iron hydroxide, but in all cases heavy deposits of iron hydroxide or basic iron sulphate are present.

Between two points in the Loxley Valley about two miles apart, some twelve streams were carefully examined. The following analytical figures (see table) are typical for the water from one of the streams.

The acidity in terms of sulphuric acid varies from 8·57 to 155·57 parts per 100,000, and the total solids in solution from 47·0 to 521·0 parts per 100,000. It will be seen from the analyses that the water initially contains iron chiefly as ferrous sulphate, which at the point of discharge to the river has undergone practically complete oxidation.

	Parts per 100,000. (1)	(2)	(3)
Total solids	260·7	410·0	521·6
Solids in suspension:			
Total	5·7	Nil.	Nil.
Mineral	3·5	—	—
Solids in solution:			
Total	255·0	410·0	521·6
Mineral	163·0	372·0	480·3
Acidity (as H_2SO_4)	49·0	78·4	112·7
Iron, total	23·1	13·4	53·0
„ ferric	20·3	10·2	33·0
„ ferrous	2·8	3·2	20·0
Hardness (as $CaCO_3$)	146·8	200·3	—

	Ochre water at entrance to ganister pit, Bower Plantation.	Ochre water taken at point of entry into river.
	Parts per 100,000.	
Total solids	64·0	506·0
FeO	8·6	68·2
Fe_2O_3	22·4	64·9
CaO	15·0	19·0
MgO	17·3	14·4
SO_3	125·7	223·6

The source of the iron salts is without doubt ferric sulphide (iron pyrites) between the layers of the coal strata. Specimens of the shale and coal when first exposed show distinct layers of pyrites in the course of oxidation; in splitting the layers perfect crystals of transparent calcium sulphate in the form of selenite, $CaSO_4,2H_2O$, may be observed. This substance also finds its way into the water, as the analyses indicate.

The waters issuing from the mines contain ferrous and ferric sulphates and free sulphuric acid, the primary oxidation products of pyrites. In the streams further reactions occur producing the heavy red deposits which consist of ferric oxide and basic ferric sulphates. In some cases the banks consist of this deposited ochre for several inches in depth.

The ochre deposits have their origin in several ways: (1) Direct oxidation and the production of ferric hydroxide; (2) alkaline surface waters joining the stream; (3) the action of iron bacteria, which grow profusely in such waters.

The first two methods of deposition are purely chemical; the third is of considerable interest. Water containing iron salts, even in very minute quantities, forms a very suitable medium for the growth of the organisms commonly referred to as "iron bacteria"; two common varieties of these are *Crenothrix polyspera* and *Leptothrix ochraceæ*. As little as one part of iron in 2 to 3 millions of water is sufficient to permit the development of these organisms. The organisms decompose the salts of iron, depositing the iron in the form of ferric oxide, the liberated acid then attacking the iron of the water pipes. Serious corrosion may occur in this manner.

In the case of ochre streams such as those under consideration the organisms deposit the ferric oxide and the streams become acid. The organisms have very high chemical energy and are able to oxidise ferrous salts many times the weight of their own cells. They are remarkable by reason of the fact that their existence is maintained largely by inorganic salts and the presence of only minute quantities of organic matter is necessary. In the case of the two rivers mentioned the usual flora and fauna are entirely absent.

It will be apparent that the industrial users of waters of rivers into which ochre streams discharge must be subject to great inconvenience and expense. Such waters must be neutralised and

softened before use, or serious corrosion of boilers, pipes, tanks, and iron and steel work will generally occur.

In the case of the rivers under consideration a pure stream of water is within two miles rendered practically unsuitable for industrial use of any kind, except after treatment. Such discharges cannot in any way be controlled or purification insisted upon, as waters draining from mines are specifically excluded from control of rivers authorities under the various Rivers Pollution Prevention Acts.

Discussion.

Mr. W. McD. Mackey mentioned the case of a water supply containing traces of iron as bicarbonate, which after flowing about 100 yards in a shallow stream, became free from iron.

Mr. C. P. Finn gave an instance of an ochre water derived from a disused coal pit, which, unlike the waters tested by the authors, was invariably alkaline. It was quite clear when first pumped, but immediately commenced to precipitate ochre when turned into the stream. In twelve months about 100 yards of pump main was reduced in effective diameter from 10 in. to 2 in. by the deposit.

The Chairman instanced a water supply at Blackburn which contained a small amount (some 0·3 part per 100,000) of iron, which was sufficient to cause "iron spots" on dyed fabric. Its elimination was attended by considerable difficulty, attributed to the presence of the tannin substances. It had finally been found necessary to harden the water, soften it, and then treat with permutit.

Dr. Chaplin said that in his experience with Wakefield water organic matter high in nitrogen delayed the softening process, and the organic matter tended to keep iron in solution.

Mr. Evans, in reply to a question, said that the determination of acidity in the presence of iron was difficult, and that so far the authors had found no method that was entirely satisfactory. With reference to bacterial deposits in water mains, he recalled the trouble experienced in conveying water from Lake Vyrny to Liverpool, which had been overcome by efficient filtration at the lake.

Mr. Haigh Johnson said he had found that the bacterial growths in cast-iron water mains were generally confined to places where manganese was present, and he concluded that manganese was essential for the development of these bacteria.

Mr. A. R. Tankard suggested that the acidity in presence of iron might be estimated by titration with standard lime-water, using phenolphthalein as indicator.

Dr. Lloyd thought that it might be better to replace the phenolphthalein by Congo red dyed a pale shade on silk.

Mr. Lowson mentioned the hydrogen sulphide method for estimating free acid in the presence of iron.

Mr. Haworth said that manganese was always present in small quantities in the waters they had examined.

Communications.

SOME METHODS OF PURIFICATION OF o-TOLUENESULPHONAMIDE.

BY PHYLLIS VIOLET MCKIE.

In the preparation of saccharin from toluene two nearly related routes (Fahlberg, G.P. 224,386, *et seq.*; and Lange, G.P. 57,391 *et seq.*) may be followed. In the Fahlberg procedure the initial stage gives rise to a mixture of *o*- and *p*-sulphochlorides in the ratio of 60:40, while in the alternative Lange process a mixture of *o*- and *p*-sulphonic acids in the same ratio is obtained. The essential difference is that separation of the *ortho* and *para* derivatives is performed in the latter process at the sulphonic acid stage, and in the Fahlberg process partly at the chloride, partly at the amide stage. By partial separation of the chlorides a mixture containing 70% *o*- and 30% *p*-sulphonic chloride is obtained, and these proportions are maintained during the subsequent amidation.

Several methods have been devised by which the proportion of *para* component in this 70/30 *o*-*p*-amide mixture can be reduced:—(1) Precipitation by acids from alkaline solution (G.P. 76,881, 1892). (2) Separation based on the fact that of the crystalline salts formed with alkalis, that of the *ortho* compound is the less soluble (G.P. 77,435, 1894). (3) Precipitation from alkaline solution by ammonium salts (G.P. 154,655, 1903). A fourth process, which involves the transformation of the amides again into the sulphonic chlorides, has also been used (G.P. 133,919, 1902).

In no case do these patents claim complete separation. A certain amount of *o*-toluenesulphonamide, still mixed with 7—10% of *para* component, and hence of only 90—93% purity, is extracted, while the residual mother liquor contains, besides the bulk of the *p*-toluenesulphonamide, a varying proportion—up to 30%—of the *ortho* isomer. Oxidation of the mixture containing only 90% *ortho* compound thus produces a saccharin of equal impurity.

On the other hand, separation of the *ortho*- and *para*-toluenesulphonic acids in the Lange method of preparing saccharin produces an acid containing already 90% of *ortho* compound. Subsequent chlorination and amidation of this acid thus yields a crude *o*-toluenesulphonamide mixed with only 10% *para* compound.

It was the object of this investigation to examine and test a number of simple methods of freeing the *o*-toluenesulphonamide from this 10% of *para* derivative, which remains after the preliminary separation of the 70/30 mixture by the patented processes. Especial emphasis is laid on the avoidance of loss of *o*-toluenesulphonamide in the purification.

Crystallisation from water.

(The solubility in water of *o*-toluenesulphonamide is 1 part in 958 parts at 9° C.; *p*-toluenesulphonamide, 1 part in 515 parts at 9° C. Klason, Vallin. Ber., 1879, 12, 1851.)

One recrystallisation of the crude (90% pure) amide mixture from water sufficient to retain the whole of the contained *p*-toluenesulphonamide in solution yields 80% of *o*-toluenesulphonamide of 97—98% purity.

Table I.

Initial mixture.		Recrystallised material.	m.p.	Purity.
5 g.			150°	90%
	1st	4 g.	155°	98%
	2nd	3·6 g.	155·2°	98·3%
	3rd	3·06 g.	155·5°	99·2%

Only by fractional sublimation *in vacuo* could the melting point be raised above that obtained by a third recrystallisation from water. (The melting point of pure *o*-toluenesulphonamide is 156·3° C. McKie. Chem. Soc. Trans., 1918, 113, 799.)

Precipitation by acids from alkaline solution.

In considering the separation of *o*- and *p*-toluenesulphonamides from alkaline solution, or the extraction of the solid amides by aqueous alkali, two opposing factors have to be taken into account. Of the two amides the *ortho* compound is the less soluble, as is also the sodium salt of the *ortho* amide, but *o*-toluenesulphonamide should, by virtue of its configuration, possess the greater " acidity " (*cf. o*-chlorobenzoic and *o*-nitrobenzoic acids, which are much stronger acids than the corresponding *para* derivatives).

The solid toluenesulphonamide mixture, containing 90% *ortho* and 10% *para* derivative, was dissolved in a solution of one mole of 8—10% sodium hydroxide. Addition of acids of varying strengths and in varying proportions precipitated corresponding amounts of solid toluenesulphonamide, which was collected, dried, and weighed in a Gooch or alundum crucible. As there is always a slight loss in the steam oven, the solid was dried over sulphuric acid *in vacuo* at 50° C.

(i) *Acid equivalent to one-tenth of o-toluenesulphonamide:*—Addition of acid equivalent to one-tenth of the *o*-toluenesulphonamide brings out almost completely pure *ortho* compound, largely independent of the hydrion concentration of the acid. Except for very low concentrations of hydrion, solubility is the most powerful factor, and hence the less soluble—the *o*-toluenesulphonamide—is precipitated only very slightly contaminated with *para* derivative. But with such a slightly ionised acid as carbonic acid the relative acidities of the two toluenesulphonamides come into play, though solubility is still dominant, hence a small amount (3% by carbonic acid) of *p*-toluenesulphonamide is precipitated.

TABLE II.

5 g. of mixed toluenesulphonamide, containing 10% *p*-toluene sulphonamide, in 1 mole (1·17 g.) NaOH in 15 c.c.
Acid equivalent to *p*-toluenesulphonamide added in 10 c.c. of water.

Acid.	Hydrochloric	Acetic.	Carbonic.
Wt. amide precipitated..	0·53 g.	0·5263 g.	0·4820 g.
Melting point	156°	155°	154·5°
% o-toluenesulphonamide in precipitate	99·5	98	97

(ii) Experiments were made in which amounts of hydrochloric and acetic acid equivalent to 70% of *o*-toluenesulphonamide were added to solutions of mixed amide containing 10% of *para* compound, in one mole of 8—10% sodium hydroxide. After standing for some hours the precipitated solid was filtered off. A second and third separation was obtained by addition of acid respectively equivalent to 15% and 9% of *o*-toluenesulphonamide.

TABLE III.

	Hydrochloric acid.	Acetic acid.
Wt. mixed amide, m.p. 150°	5 g.	5 g.
Acid=70% of o-amide.		
Amide precipitated ..	3·2 g.	3·158 g.
Melting point ..	154°=(96% *o*-amide)	156°=(99·5% *o*-amide)
Acid=15% of o-amide.		
Amide precipitated ..	0·65 g.	0·65 g.
Melting point ..	150°=(90% *o*-amide)	155°=(98% *o*-amide)
Acid=9% o-amide.		
Amide precipitated ..	—	0·489 g.
Melting point ..	—	149°=(87·5% *o*-amide)

As will be seen from the table, the weaker acid, acetic, gave a precipitation of *o*-toluenesulphonamide, containing only 0·5% of *para* component, and representing 65% of the total amide originally used. By addition of acetic acid equivalent to a further 15% of *o*-toluenesulphonamide a solid still containing 99% of *ortho* component was obtained.

On the other hand, the strong acid, hydrochloric acid, gave in the first separation a solid containing 3% of *p*-toluenesulphonamide, and in the second (using acid equivalent to 15% *o*-toluenesulphonamide), a mixture containing 10% of *para* derivative. Hence it is obvious that too high a concentration of hydrion so puts back the ionisation of each of the amides that their relative acidities cease to be operative, and the amides are precipitated in a proportion dependent solely on their relative solubilities.

Extraction of the solid mixture by alkali.

The solid toluenesulphonamide mixture was ground up with the requisite quantity of aqueous alkali at a temperature of 50° C., and shaken at that temperature at intervals for three hours. It was then left at room temperature for sixteen hours, after which it was filtered.

A comparison on these lines between sodium hydroxide and sodium carbonate showed conclusively that the weaker alkali, sodium carbonate, effects a cleaner separation than does the stronger sodium hydroxide, and the recovery of pure *o*-toluenesulphonamide is therefore higher.

TABLE IV.

10 g. mixed toluenesulphonamides, containing 10% *p*-toluenesulphonamide. m.p. 150°.

	NaOH.	Na_2CO_3.
Alkali (conc. 1·17%)=*p*-amide	0·234 g.	0·308 g.
Amide undissolved	8·74 g.	9·374 g.
Melting point	152·5°	153·5°
% *o*-amide in undissolved amide	93·5	95

If the concentration of the alkali be increased, relatively more *p*-toluenesulphonamide is extracted, and hence the undissolved amide contains a higher proportion of *ortho* compound. But the loss (dissolved material) increases with increase of concentration, so that the higher the concentration of the alkali, the less is the total remaining amide (*v.* Table V). While at a concentration of 7·7% alkali, extraction with two moles of sodium carbonate yields a slightly purer *o*-toluenesulphonamide than does a concentration of 2·3%, nevertheless the percentage of dissolved solid is double that at the lower concentration.

TABLE V.

Effect of concentration.

Mixed amide taken, 10 g. (90% *o*-amide). m.p. 150°.

Concentration of Na_2CO^3.	1·17%.	2·3%.	7·7%.
Undissolved amide ..	9·38 g.	9·28 g.	9·02 g.
Melting point	153°	153·5°	154°
o-amide in undissolved solid	94%	95%	96%
Amide from mother liquor by acidification	0·3 g.	0·3 g.	0·29 g.
Melting point	115°	109°	117°
p-amide present.. ..	66%	60%	68%
Loss	3%	4%	6%

Extraction of the solid mixture with aqueous alcohol.

(1 part *o*-toluenesulphonamide dissolves in 28 parts of alcohol, 1 part *p*-toluenesulphonamide dissolves in 13·5 parts of alcohol at 5° C. Klason, Vallin. *Ibid.*)

The mixed toluenesulphonamides were ground up with 96% alcohol, sufficient to dissolve the whole of the contained *p*-toluenesulphonamide. A residual solid representing 83·8% of the total material, but containing only 95% of *o*-toluenesulphonamide, was thus obtained.

The use of 50% aqueous alcohol is more successful. The undissolved amide, which represents 93·5% of the *o*-toluenesulphonamide, in the original mixture, consists of 98% of *o*-toluenesulphonamide and 2% of *p*-toluenesulphonamide.

TABLE VI.

10 g. mixed toluenesulphonamide, containing 1 g. *p*-toluenesulphonamide.

	96% alcohol.	50% alcohol.
Amide undissolved	8·38 g.	8·403 g.
Melting point	153·5°	155°
o-amide in undissolved amide	95%	98%

Purification by partial oxidation.

In that process of oxidation of *o*-toluenesulphonamide to saccharin in which *o*-toluenesulphonamide in excess of potassium permanganate is used (E.P. 3563, 1903), the excess amide is isolated as completely pure *o*-toluenesulphonamide. Any *p*-toluenesulphonamide present is oxidised to *p*-sulphaminobenzoic acid. Application of this procedure as a means of purification of a 90% mixture of *o*- and *p*-toluenesulphonamides was highly successful. 90—94% of the *o*-toluenesulphonamide was obtained in a high degree of purity. In the process saccharin of a like degree of purity, equivalent to 5—9% of *o*-toluenesulphonamide, is also isolated. Hence the total loss—unrecovered material—is only the 10% represented by the initial *para* component.

Economically, however, the loss of permanganate necessitated by this procedure is an important factor. The saccharin isolated represents only 60% of the potassium permanganate reduced.

TABLE VII.

10 g. mixed toluenesulphonamide, containing 1 g. *p*-toluenesulphonamide.

Potassium permanganate equivalent to 1 g. *p*-amide = 1·84 g.

Unoxidised amide	= 8·1 g.	m.p. 155·5° = 99·2% *o*-amide
Saccharin	= 0·93 g.	m.p. 226° = 0·87 g. „
Loss—*i.e.*, unrecovered material ..	= 1·03 g.	

The *o*-amide is represented by 99·2% of 8·1 g. unoxidised = 8·0595 g. and saccharin equivalent to 0·87 g., or a total of 8·9295 g. Hence the loss of *o*-toluenesulphonamide is 0·07 g.

Conclusions.

Consideration of the results of the various methods of separation of *o*- and *p*-toluenesulphonamides shows that certain processes stand out as yielding a product of greater purity and with a minimum loss.

In every case final purification, brought about by repeated recrystallisation from water, followed by sublimation *in vacuo* is required.

The highest degree of purity which can be obtained is effected by precipitation by acetic acid of 70% of the *o*-toluenesulphonamide from an alkaline solution of the mixed amides; a product containing 99·5% of *o*-toluenesulphonamide is thereby obtained. But the loss involved is very high—30% of the *ortho* compound.

Purification by partial oxidation gives, on the whole, the most satisfactory results. A product of a high degree of purity—99%—is obtained, and including the saccharin which is isolated, represents the whole of the valuable *o*-toluenesulphonamide, a fact of immense importance in the manufacture of saccharin. But the many and lengthy operations involved, and the fact that for every one part of *o*-toluenesulphonamide recovered 0·216 part of potassium permanganate is destroyed, and of this 40%, or 0·086 part, is not accounted for by any product isolated, somewhat detracts from the advantages which this method possesses.

For simplicity and rapidity of manipulation, combined with a good yield of *o*-toluenesulphonamide of a high degree of purity, one extraction of the mixture with 50% aqueous alcohol (1 part of mixed amide to 5 parts of 50% alcohol) is to be recommended. By this means 90·7% of the *o*-toluenesulphonamide of 97% purity is extracted.

Extraction of the mixture with a moderately concentrated solution of sodium carbonate, while it does not effect such a clean separation (the *o*-toluenesuphonamide is of only 96% purity), brings out almost the whole of the *ortho* compound; a loss of but 2—3% is involved.

On these grounds, together with its low cost and ease of manipulation, it may be suggested as an admirable means of separating mixtures containing more than 10% *para* compound, and even of the "⅔—⅓" mixture obtained in the Fahlberg saccharin process.

I desire to express my indebtedness to Professor Orton, under whose direction this work has been carried out.

THE VOLATILE OIL FROM THE LEAVES OF THE "WILD PIMENTO" OF JAMAICA.

BY O. D. ROBERTS, F.I.C.

The genus *Pimenta* includes two species which are well known in commerce as sources of volatile oils. These are (1) *P. officinalis*, the unripe fruit of which yields ordinary pimento or allspice oil, whilst the leaves also furnish an oil of similar composition; and (2) *P. acris*, from the leaves of which commercial oil of bay is obtained.

Two volatile oils from the leaves of sub-varieties of *P. acris* have also been examined, viz., oil of *P. acris* var. *citrifolia*, Kostel, which is said to contain an appreciable quantity of citral, and oil from a form of *P. acris*, known as "Bois d'Inde anise," which has a characteristic anise-like odour.

The oil which is the subject of the present investigation differs widely in composition from any of the above oils, and has an odour recalling that of spike lavender oil. It is derived from the leaves of a species of pimento found in Jamaica, both in the woods of Upper Clarendon at an altitude of 2000—2500 feet, and in the Dry Harbour Mountains. The tree attains a height of 40 feet and its trunk a diameter of 1 foot. The species is locally known as "Wild pimento," and has been named *Amomis* (= *Pimenta*) *jamaicensis*, Britton and Harris, by the Government botanist.

Leaves distilled in Jamaica were stated to have yielded 0·49% of oil. A sample of the oil received at the Imperial Institute from the Director of Agriculture of Jamaica in 1918 was pale yellow, and had an odour somewhat resembling that of the oil of *Lavandula spica*. It had the following constants: sp. gr. (15°/15° C.) 0·8895; α_D^{22} (in a 100 mm. tube) = −6° 0′; n_D^{20} = 1·471; acid value 2·4; ester value before acetylation 4·2; ester value after acetylation 129·4. The oil was soluble in 2·5 volumes of 70% alcohol at 15° C., becoming cloudy with 6 volumes.

The following results were obtained in a systematic investigation of the oil.

Free acids: Indication of the presence of caproic and acetic acids.

The free acids were extracted from the oil by shaking it with a dilute solution of sodium carbonate. On acidifying the solution and extracting with ether, an amount equivalent to about 0·2% of the original oil was obtained. This acid liquid was distilled in a current of steam, when there separated in the distillate a small quantity of an acid substance having an unpleasant odour resembling that of caproic acid. After separation from the aqueous portion of the distillate, this substance was converted into its silver salt, of which 0·1270 g. gave 0·0617 g. Ag (Ag=48·6%). Silver caproate contains 48·4% Ag. The aqueous portion of the distillate was saturated with calcium chloride, washed with ether, and again distilled in a current of steam. The distillate contained a readily soluble acid; 0·1023% of its silver salt gave 0·0657 g. Ag (Ag=64·2%). Silver acetate contains 64·6% Ag.

Aldehydes.

On shaking the oil with a saturated solution of sodium hydrogen sulphite, combination to the extent of about 0·1% of the original oil took place. The substance thus removed from the oil had a rather pleasant odour, and was aldehydic in character, for it responded to Schiff's rosaniline test. The amount of liquid obtained was not sufficient for further investigation.

Phenols. Absence of eugenol.

The original oil, after the foregoing treatment with sodium carbonate and sodium hydrogen sulphite solutions, was extracted with a 3% solution of sodium hydroxide. A phenolic liquid was obtained which amounted to about 0·1% of the original oil. This substance had a slight phenolic odour, and produced a reddish-violet coloration with a solution of ferric chloride, but no evidence of the presence of eugenol was obtained.

Fractional distillation of the oil.

Before proceeding with the fractional distillation of the oil remaining after the removal of the above-mentioned traces of free acids, phenols, and aldehydes, the oil was hydrolysed by boiling it with alcoholic potassium hydroxide. After the greater portion of the alcohol had been removed by distillation, sufficient water was added to effect the separation of the oil, which was extracted with ether, the ethereal solution was washed and dried, the ether removed, and the oil submitted to repeated fractionation. The following fractions were obtained:—

	Per cent. calculated on the original oil.	Range of boiling point.		Sp. gr. (15°/15° C.)	α_D^{18} 100mm. tube.	n_D^{20}
		Under 14 mm. pressure.	Under atm. pressure.			
1.	32	75°– 80°	175°–190°	0·8750	−8·25°	1·4720
2.	42	80°– 95°	190°–205°	0·8677	−3·74°	1·4670
3.	4	95°–110°	205°–220°	0·8808	−2·30°	1·4705
4.	6	110°–125°	220°–235°	0·9010	−3·80°	1·4865
	Residue 16	—	—	0·9592	Too dark to obtain a reading.	1·5205

Identification of cineol.

The fraction boiling at 175°—190° C. was a colourless limpid liquid, having a camphoraceous odour. On treating it with a 50% solution of resorcinol, an absorption of 47% was obtained, equivalent to 15% of the original oil. The remaining oil was separated from the clear resorcinol solution, and the latter was then subjected to distillation with steam. The colourless oil, which separated in the distillate, had the characteristic odour of cineol, was optically inactive, had sp. gr. (15°/15°) 0·9270, and furnished a pale greenish-white iodole addition compound, which melted and decomposed at 116° C. It was evident therefore that the portion of this fraction absorbed by the resorcinol solution consisted practically entirely of cineol.

Identification of α-phellandrene.

The part of this fraction (175°—190°) which was unabsorbed by the resorcinol solution was distilled over sodium under reduced pressure, and a colourless mobile oil was thus obtained which had sp. gr. (15°/15°) 0·8520, α_D^{22} (in a 100 mm. tube) = −11° 42′; b.p. 172°—179° (uncorr.). A portion of this oil, treated with sodium nitrite and glacial acetic acid, gave the characteristic reaction of phellandrene. The nitrite, after crystallisation from methyl alcohol and chloroform, melted at 112°—113° C., thus establishing the presence of α-phellandrene in the oil.

Identification of dipentene.

From another portion of the above oil, boiling at 172°—179°, a fraction boiling at 176°—179° was obtained, which furnished a tetrabromide melting at 124° C., thus proving the presence of dipentene.

Identification of linalool.

The fraction boiling at 190°—205°, which was the largest fraction obtained, consisted of a colourless liquid, with a pronounced odour of linalool. Almost the entire fraction boiled at 197°—198° C.; this portion had sp. gr. (15°/15°) 0·8693, α_D = −3° 39′, n_D^{20} = 1·4655, which are the characteristic physical constants of linalool. A portion was gently oxidised with chromic acid mixture, and the resulting oil, after purification by distillation with steam, was treated with sodium hydrogen sulphite solution. From the solid bisulphite compound thus produced, citral was liberated, which was recognised by its odour, and identified by the preparation of crystalline α-citryl-β-naphthacinchoninic acid, m.p. 200° C. From these results it is evident that this fraction consisted almost entiredy of *l*-linalool.

The small fraction boiling at 205°—220° C. was a colourless liquid, possessing a pleasant aromatic odour. The alcoholic nature of this fraction was evidenced by its almost complete esterification when treated with acetic anhydride; the combination which took place on heating a portion with phthalic anhydride was, however, almost negligible, thus indicating that the substance consisted of a tertiary alcohol. It was clear that this fraction also consisted largely of linalool, and no definite indication of the presence of any other alcohol was obtained.

Identification of geraniol.

The fraction boiling at 220°—235° consisted of a colourless liquid, possessing a faint rose-like odour. When a few drops of this fraction were oxidised with chromic acid mixture the strong odour of citral was developed. The fraction, diluted with an equal volume of benzene, was heated for several hours with phthalic anhydride. The acid phthalic ester thus formed was converted into the sodium salt which, on saponification and simultaneous distillation in a current of steam, furnished an oil having the characteristic odour of geraniol. The presence of geraniol was confirmed by the formation of geraniol diphenylurethane, m.p. 80°—81° C.

B

The fraction boiling above 235° was brown and rather viscous. It was evident that it contained resinous decomposition products, consequent upon distillation of the oil under atmospheric pressure. With the object of ascertaining whether any characteristic sesquiterpene was present, this fraction was heated on the water bath for some weeks with sodium under reduced pressure. The oil was then distilled off under 15 mm. pressure. There was thus obtained a colourless oil, with a slight balsamic odour, having sp. gr. (15°/15°) 0·9320, and boiling between 245° and 290° (uncorr.) at atmospheric pressure. Its high density, wide range of boiling point, and the fact that the oil was still slowly attacked by sodium, showed that appreciable quantities of oxygenated compounds were still present. The amount of oil was too small to permit of any further investigation of this fraction.

Summary.

The results of this investigation of the volatile oil from the leaves of *Amomis jamaicensis* have shown that its composition is approximately as follows:—Terpenes, including α-phellandrene and dipentene, 17·0%; cineol, 15·0%; aldehydes, undetermined, 0·1%; alcohols, chiefly *l*-linalool with some geraniol, 38·3%; esters, as linalyl acetate, 1·5%; phenols, undetermined, 0·1%; acids (acetic and caproic in the free state), 0·2%; residue probably containing sesquiterpenes, 27·8%.

NOTE ON A SPECIAL SLIDE RULE FOR CALCULATION OF "WET" AND "DRY" WEIGHTS OF DAMP MATERIAL.

BY R. SCOTT.

The necessity for a simple, rapid, and accurate method of calculating the "wet" and "dry" weights of nitrocellulose batches led to the construction in this laboratory of a calculator which has proved useful, and the principle employed seems to offer a wider scope for practice.

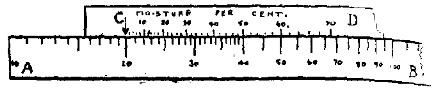
A slide rule may be used in many cases where a nomographic or alinement chart has been suggested for routine calculations. It is easily constructed and easily manipulated, and the time required for the calculation is reduced to a few seconds.

In handling a batch of damp material it is customary to have a sample submitted for determination of moisture which is expressed as moisture per cent. of the damp material. There is now required the amount of "wet" material to give a specific amount of "dry" or the "dry" content of a certain amount of "wet."

The calculation is given by

$$D \times \frac{100}{100-M} = W$$

where D=dry weight, W=wet weight, and M=moisture per cent. This is of the general form XY=Z and capable of slide rule or nomographic treatment.



To make the slide rule the frame scale, A B (see fig.), was divided in the usual logarithmic manner but the slide scale, C D, was divided proportionally to log. 100/(100—M) between suitable limits of M, each division being marked with its appropriate value of M. The frame scale, A B, was extended beyond the point marked 100 by a length equal to the total length of the slide scale.

For wet weight determination the zero mark on C D is placed opposite the division on A B corresponding to the "dry" weight, and the "wet" weight read off opposite the division on C D marked with the moisture content. For "dry" weight determination the process is reversed.

A convenient distance between the points marked 10 and 100 on the frame was found to be 1000 mm.

The wooden frame and slide were constructed in the carpenters' shop and made so that C D could be moved easily along A B. The scales were glued to the wood and coated with celluloid varnish. The whole apparatus measured 4′ 9″×3½″×¾″.

The accuracy of the instrument, assuming careful construction, will depend on the scale on which it is constructed and the number of divisions introduced. The calculator in use has a total maximum apparent error due to size of scale divisions of 0·56 lb. dry weight on 100 lb. of dry material, but this is due to errors accumulating in the same direction. In practice the reading of figures may be made to approximations, where necessary, between divisions, and the error thus maintained well within the limit.

It is easy to modify the slide scale to read weights where a certain percentage of moisture is allowed, as in air-dry material. The slide in this instance would be divided proportionally to log. (100—a)/(100—M), where a is the percentage of moisture allowable.

In general a similar instrument should be useful for rapid calculations of the type $a=x.\mathrm{f}(y)$, with the slide scale divided in proportion to log. f(y).

By using several slides, equations of the type $\phi(a)=\mathrm{F}(x).\mathrm{f}(y)$. . . may be solved by dividing the frame scale proportional to log. $\phi(a)$ and slide scales proportionally to log. F(x) and log. f.(y). . .

Communications.

SOME PROPERTIES OF TETRANITRANILINE (TNA).

BY B. J. FLÜRSCHEIM, PH.D.

Since the appearance of the first publications on TNA[1] many authors or patentees have dealt with the subject. Additional information of value has resulted in some cases, whereas erroneous or incorrect statements have been made in others, and it may therefore be useful to give a brief review of the subject on the basis of seventeen years' personal experience. The present communication will therefore deal with the constitution and reactions of TNA, its density and colour, stability, physiological properties, power, and sensitising properties, and certain points connected with its manufacture. Of the tests recorded below, in all of which, unless otherwise stated, merely water-washed, unrecrystallised TNA manufactured on plant scale has been used, Nos. 2, 4—8, 14—16, 22, 26—29, 42, 43, 49—51, 58—60, and 64 were carried out by Allied and associated Governments, Nos. 9, 21, 25, 30, 35, 56, 57, 62, 63 (partly), by explosives manufacturers, Nos. 44, 52, 55, and 61 by ordnance manufacturers, Nos. 3, 10—13, 17—20, 23, 24, 31—34, 36, and 63 (partly) by the author, and the remainder are quoted from the literature on the subject.

I.—Constitution and Reactions of TNA.

TNA was first prepared and analysed by the author in 1904, and the work was partially repeated by his assistant, T. Simon, in 1906. The determination of the positions occupied by the nitro-groups was carried out by the author in 1910, both by synthesis from derivatives of aniline containing a second nitro-group in an ortho- or para-position with regard to the amino group,[2] and by the conversion of TNA into compounds already known, notably trinitroresorcinol[3] and trinitro-*m*-phenylenediamine.[4] It was thus definitely proved that the nitro-groups occupy the positions 2.3.4.6, that the 3-nitro-group is mobile,[5] also that all are real nitro and not nitrite groups, for otherwise ammonia could not transform TNA to trinitro-*m*-phenylenediamine, but only to an ammonium salt of an aminophenol.

In order to test the nitro-formulation of the mobile group in the 3-position, Van Duin[6] recently reduced TNA by means of titanous chloride, and his results confirmed the already well-established fact. It had already been stated[7] that the mobile nitro-group can be replaced by numerous other radicles—for instance, by reaction with alcohols, phenols, or amines—and that the amino-group can be acetylated, and acetyltetranitraniline, trinitroaminophenol, -anisol, and -phenetol had been described. These compounds were again prepared by Van Duin,[8] as well as some of the amines.[9].

[9] Rec. Trav. Chim., 1919, **38**, 89. Van Duin's melting points are corrected for the exposed stem, whereas those previously given by the author are the usual uncorrected ones.

II.—Density and Colour.

The true colour of TNA is a strong yellow, which always appears in the ground material. Larger crystals, however, exhibit a deeper hue, varying, according to the mode of preparation, from an intense yellow to greenish. The micrograph obtained by Col. C. G. Storm, at the U.S. Bureau of Mines,

at an enlargement of 34 diameters, reveals a flaw in the crystals, and under the microscope the centre of the crystal, with the flaw, appears yellow, the transparent surrounding portion green.

Crystals without a flaw can be obtained under certain conditions of nitration, and these, under the microscope, appear entirely transparent and green. According to the method of nitration the material in bulk, as separated from the spent acid, therefore appears—without a flaw—greenish, and has an absolute density of quite 1·9, or more or less yellow, with a corresponding decrease of the density to anything between 1·9 and 1·86. This observation is chiefly due to Dr. Beardsley, of Bound Brook, N.J.

The absolute density of TNA therefore equals that of ammonium perchlorate (1·89). The absolute densities of all other organic high explosives and of ammonium nitrate lie approximately between 1·6 (nitroglycerin) and 1·77 (trinitrochlorobenzene).

III.—Stability and Reactivity.

As early as 1914 W. Macnab,[10] on the basis of several years' personal experience, was able to state that TNA "combines an exceptional explosive power with aromatic stability." Indeed, no TNA which the author has examined since its discovery in 1904, including even the very first impure samples, has proved unstable in the sense of being unsafe to handle or store. But to produce a material capable of satisfying all the more or less sensitive tests (which were really intended, not for purely aromatic products like TNA or TNT, but for wholly or partly aliphatic nitro-compounds capable of catalytically accelerated spontaneous decomposition, such as nitrocellulose, nitroglycerin, tetryl, etc.) has required the accumulated experience of several years, but has now been achieved on a commercial scale and without any purification of the material other than washing with water.

[10] Lectures on explosives, Institute of Chemistry, pp. 25, 60 (1914).

Typical examples of different TNA stability tests are given below, and the results are subsequently interpreted and compared with those obtained from other nitro-explosives.

A.—Abel test.

From each test the approximate percentage of NO_2 which would be evolved per year if the measured initial rate were maintained has been calculated by Robertson and Smart's formula.[11]

No. 1, carried out by Van Duin and Van Lennep[12] with TNA prepared with KNO_3, and re-crystallised from acetic acid. Used 10 grams in closed containers of 29·3 c.c. capacity, heated without test paper; times given are those after which an inserted starch-zinc iodide test paper is coloured in 30 seconds.

Temp.	Time.	NO_2% per year.[13]
70° C.	3 hrs.	0·044
60° C.	26 ,,	0·0051
50° C.	404 ,, †	0·00033
32° C.	1512 ,,	0·000087

† 2 samples out of 4.

No. 2, heated with test paper according to standard American Abel-test method, temperature 65·5° C.—

(*a*) Standard plant TNA, dried on plant scale 6 hrs. at 80° C. in a partial vacuum of 26—27 in. (4 samples): 4 hrs. 13 min. *plus*; NO_2<0·0007% per annum.

(*b*) Similar material, original moisture content 0·22%, dried only 1 hr. at 80° C. at ordinary pressure, tested a few days after manufacture: 30, 50, 51 min.; NO_2 av. 0·02% p.a.

(*c*) Same material as (*b*), not dried: 17, 26, 41 min.; NO_2 av. 0·05% p.a.

(*d*) Similar material, not dried, after 9 months' ordinary storage (3 samples): Slight test after 68 min., no increase of tint in further 33 min.; NO_2 0·009% p.a.

(*e*) Same material as (*a*), after adding a drop (*ca.* 5% of water): 12½, 12½ min.; NO_2 0·26% p.a.

(*f*) Same material as (*e*) after re-drying for 1 hr. at 100° C.: 60 min. *plus*; NO_2 <0·01% p.a.

No. 3. Plant TNA, which had been stored 6½ years, with a moisture content of 0·49%, was used and American Government potassium iodide test paper:—

(*a*) Pre-dried 4 hrs. at 60° C., whereby moisture was reduced to 0·26%. 10 g. TNA, test tube of 39 c.c., temp. 95° C., heated with moist test paper: av. 15 min.; NO_2 0·05% p.a. at 95° C.

(*b*) Pre-dried 4 hrs. at 95° C., 10 g. TNA, temp. 95° C., test tube 39 c.c., heated with moist test paper: av. 32 min.; NO_2 0·011% p.a. at 95° C.

(*c*) Pre-dried 4 hrs. at 95° C., 2 g. TNA, heated by Van Duin and Van Lennep's method, without test paper, test tube 25 c.c., 24 hrs. at 100° C.: av. 1 min.; NO_2 0·013% p.a. at 100° C.

(*d*) Same as (*c*), 6½ hrs. at 100° C.: av. 3 min.; NO_2 0·016% p.a. at 100° C.

(*e*) Same as (*c*), 6 hrs. at 100° C.: av. 4 min.; NO_2 0·013% at 100° C.

(*f*) Same as (*c*), but only 0·1 g. TNA, 2 hrs. at 130° C.: av. 1½ min.; NO_2 2·5% p.a. at 130° C.

(*g*) Same as (*f*), preheated 14 hrs. at 130° C., heated 2 hrs. at 130° C.: av. 3 min.; NO_2 1·1% p.a. at 130° C.

B.—Manometric and gravimetric heat tests.

No. 4. Gas evolution *in vacuo* of plant TNA after about 10 months' ordinary storage. Pre-dried, before test, for 4 hrs. at 60° C., 18 hrs. at 80° C.: 1st hour, 0·60 c.c. per g. per hr. at 120° C.; 2nd, 0·25; 3rd, 0·16; 4th to 7th, 0·11; 8th to 11th, 0·09; 12th to 15th, 0·07; 16th to 19th, 0·06; 20th to 30th hour, 0·052 c.c.

No. 5. Same material after about 45 months' storage. Pre-dried 18 hrs. at 30°—40° C., 2 hrs. at about 90° C.: 1st hour, 0·65 c.c. per g. per hr. at 120° C.; 2nd 0·28; 3rd, 0·24; 4th to 7th, 0·16; 8th to 11th, 0·10; 12th to 15th, 0·075; 16th to 19th, 0·06; 20th to 30th hour, 0·044 c.c.

No. 6. The same material as No. 5, after grinding and water-washing, then pre-drying as in No. 5, gave results practically identical with those of No. 5.

No. 7. Same material as No. 4, similarly predried: 1st 16 hrs., 0·034 c.c. per g. per hr. at 100° C.; 17th to 32nd, 0·020; 33rd to 48th, 0·015; 49th to 64th, 0·0125; 65th to 80th, 0·0112; 81st to 96th, 0·0106 c.c.

No. 8. TNA from an experimental run on a small plant scale, in which a mixed acid had been used containing about 2% more water than specified for standard TNA. Pre-dried 18 hrs. at 30°—40° C. and 2 hrs. at 90°—100° C.: first ½ hr., 8·8 c.c. per g. per hr. at 120° C.; ½ hr.—3 hrs., 1·28; 4th to 19th, 0·25; 20th to 27th hrs., 0·15 c.c.

No. 9. TNA made on an experimental scale[14]: 1st 4 hrs., 0·11 c.c. per g. per hr. at 120° C.; 5th to 8th, 0·075; 9th to 12th, 0·045; 13th to 16th, 0·035; 17th to 20th hrs., 0·030 c.c.

No. 10. The loss of weight of TNA (same material as No. 4, pre-heated 3 hrs. at 96° C.) was found to be as follows:—At 130·5° C., first 2 hrs., 0·113% per hr.; 2 hrs. to 9h. 40m., 0·031%; 9h. 40m. to 17h. 20m., 0·017%; 17h. 20m. to 25 hrs., 0·012%. Thereafter at 105·5° C., first 5½ hrs., 0·0012%; 5½ to 10½ hrs., 0·0012% p. hr. The same material (preheated 3 hrs. at 96° C.) lost 0·113% per hr. at 130·5° C. for the first 2 hrs., and thereafter 0·0048% per hour at 106° C. for 5 hrs. The same material (preheated 3 hrs. at 96° C.) lost 0·021% per hr. for the first 5 hrs. at 106° C.

No. 11. The same material as No. 8 (pre-dried 3 hrs. at 96° C.) during the first 2 hrs. lost 0·454% per hr. at 130·5° C.; 3rd to 4th hr., 0·130%; 5th to 6th hr., 0·108%.

No. 12. To ascertain whether aminopicric acid—the only non-volatile product formed by hydrolysis of TNA—has any effect on the change of weight of the latter when heated, a mixture of 95% of standard TNA and 5% of aminopicric acid was heated at 130° C. The % per hour decrease was identical with that obtained with the same TNA by itself. Aminopicric acid by itself, after 4 hrs.' preheating at 95° C., lost during the first 4 hrs. 0·075% per hr., and during the 5th—8th hrs. 0·048% at 130° C.

No. 13. The % per hour decrease of a mixture of 95% of TNA and 5% of aminopicric acid remained the same when the composition was finely ground to ensure intimate mixing.

C.—Fume (German) Test. 135° *C.*

No. 14. TNA was found to withstand the test (no fumes) for 60 hrs. *plus*.

No. 15. TNA which had been further dried on plant scale at 80° C. for 6 hrs. in a partial vacuum turned the blue litmus paper to a neutral pink (3 samples) after 34 min. without bleaching the dye. A fresh paper inserted thereafter was turned pink in 72 mins. (3 samples). The test paper did not lose its sensitiveness. The TNA gave no fumes and did not smell of acid.

TNA which had been pre-dried in the laboratory for 2 hrs. at 100° C. and then allowed to cool for 1 hr., turned the paper, at 135° C., to a neutral pink after 43 mins. (1 sample), and 63 mins. (1 sample). There were no fumes or acid smell.

[11] J., 1910, 132.

[12] Rec. Trav. Chim., 1920, 39, 163; Van Duin, Utrecht, Thesis, 1918.

[13] As zinc iodide test paper is more sensitive than KI paper (*cf* Marshall," Explosives," 2nd ed., p. 660) these figures are somewhat too high.

[14] A diagram of this test has been published in Z. ges. Schiess- u. Sprengst., 1918, 8, 185.

D.—Storage test at 90° F. (32° C.)

No. 16. Explosives for authorisation in Great Britain must withstand this test for six weeks.[15] TNA is on the British Home Office list of authorised explosives of January 1st, 1920, in Class 3, Division 2.

E.—Storage test at 75° C.

No. 17. TNA withstands this test, not only for the 48 hrs. prescribed by the International Commission for Unification of Explosives,[16] but for an indefinite period.

F.—French litmus tests.

No. 18. Moist neutral litmus paper is not reddened by TNA in 5 days at the ordinary temperature.

No. 19. Dry blue litmus paper is not reddened by TNA in 36 hrs. at 96° C.

No. 20 (test prescribed by French railways). Neutral litmus paper is not reddened by 100 c.c. of water with which 1 g. of TNA had been shaken for ½ hr. at 15° C.

G.—Behaviour toward metals.

No. 21. Experiments already recorded[17] have shown that TNA, whether wet or dry, does not attack steel, iron, tin, copper, brass, lead, aluminium, or zinc in 14 days at the ordinary temperature.

No. 22. TNA (moisture about 0·2%) was packed in copper caps, sealed with paraffin, and stored for 28 months at 90°—100° F. Both the TNA and the surface of the metal remained unaltered.

H.—Behaviour towards inorganic nitrates.

No. 23. 40 parts of TNA and 60 parts of commercial ammonium nitrate, neither of which had been specially pre-dried, were ground together and stored for seven years, under a glass jar, at ordinary temperature and in daylight, and excluding atmospheric moisture. No interaction had taken place, since the mixture was separated into its unchanged components by means of benzene or water.

No. 24. Compressed cartridges containing 50% of "yellow" TNA from an early experiment on semi-plant scale, 10% of potassium nitrate, and 40% of barium nitrate[18] were stored for 28 months at the ordinary temperature, with access of air moisture, and during part of this period in daylight. They remained unchanged.

I.—Resistance to water, solubility, and hygroscopicity.

No. 25. Wet TNA as manufactured retains about 20—25% of water on a vacuum filter, and less than 10% on a centrifugal. TNA with 20—25% of water was generally dried at a temperature rising slowly from 40° to 60° C. for about 24 hrs. at atmospheric pressure, or about 8 hrs. in a vacuum dryer. Its acidity was determined, both before and after drying, according to a method specified by two of the Allied and associated Governments, in which 10 g. of TNA is allowed to stand for ½ hr., with occasional shaking, in 150 c.c. of neutral water, whereafter it is filtered and twice washed with 20 c.c. of water, the united filtrates being titrated with $N/50$ sodium hydroxide, using 15 drops of a 0·5% phenolphthalein solution as indicator. The acidity obtained for standard "green" TNA generally amounted to about 0·2% calculated as H_2SO_4, and was the same before and after the drying. There is therefore no measurable hydrolysis during drying, since this would produce aminopicric acid—a strong and non-volatile acid—which would result in a higher acidity in the dry, as compared with the wet material.

No. 26. *Exposure to own moisture on storage.* The official report states: "On a sample of TNA, Lot No. 3/16, inspected in August, 1916, for . . . . I determined the acidity at that time to be 0·015%. After 9 months' dark storage of this sample, at laboratory temperature, I again determined the acidity and found it to be 0·017%. This apparent increase in acidity is within the limit of experimental error. The amount of mosture (about 0·2%) ordinarily present in TNA of regular plant manufactured does not therefore cause any decomposition of the material."

No. 27. *Acidity of TNA stored with excess of water in the absence of light.* Three tests were made as follows: 10 g. of a composite sample of ordinary green TNA was placed with 150 c.c. of neutral water in sealed rubber-stoppered bottles in a dark room and shaken occasionally and the acidity tested as described in No. 25 with the following results:—

After	Acidity.	Increased acidity per day.
1 day	0·0195%	—
2 days	0·0231	0·0036%
15 "	0·0341	0·0008
21 "	0·0354	0·0002

The above indicated that, in the dark, the acidity obtained with water is due to the gradual liberation of the occluded sulphuric acid. In further tests, in which TNA, as manufactured was allowed to stand with water for 6 mins., the acidity with unground TNA was found to be 0·034% and with the finely ground substance 0·063%. It is stated in the official report that these figures and the results of tests Nos. 28 and 29 show that the acidity is due to the removal of occluded sulphuric acid, since if it had been due to decomposition of the TNA the figures for "increased acidity per day" would have shown a rise or at least remained steady.

No. 28. *Prolonged exposure to excess of water in daylight.* A blend of green and yellow TNA, original acidity 0·0232%, showed the following increases of acidity: After 1st 24 hrs., 0·0209%; 24—48 h., 0·0270; 48—72, 0·0092; 72—96, 0·0256; 96—120, 0·0228; 120—168, 0·0392; 168—192, 0·0110; 192—216, 0·0147; 216—264, 0·0287; 264—312, 0·0140; 312—336 h., 0·0094%. Average increase of acidity per 24 hrs., 0·0159%. Two other samples showed an average increase of acidity per 24 hrs. of 0·0163% and 0·0139%. The daily variation in the increase of acidity appeared to depend somewhat on the changes of temperature. That the TNA, through the action of water at ordinary temperature, does not undergo any change that would affect its quality is demonstrated, the official report adds, by the fact that the three samples after the above tests had m.p. 212·5°, 213·0°, and 213·0° C. respectively.

No. 29. The sample of TNA which had been stored with excess of water for 13 days without complete exclusion of light was dried at 60° C. and then heated for one hour at 100° C.

(*a*) Abel test at 65·5° C.; 3 specimens. The test paper was not coloured in 1 hr. 50 min., whereupon the test was discontinued.

(*b*) Heat test at 136°—140° C.; 4 specimens. The first indication on the litmus paper of a change from blue to neutral pink appeared after 17 minutes. After an additional 58 mins. (viz., a total heating of 1 hr. 15 min.) the papers had entirely changed to a neutral pink, with the exception of a strip on the margin of each, which had originally been more intensely blue than the rest of the paper, and which

[17] Z. ges. Schiess- u. Spreng., 1913, 8, 185.
[18] These cartridges were exhibited by W. Macnab in his lecture on Explosives (*loc. cit.*).

remained blue. The TNA gave no fumes and did not smell of acid.

These tests are, states the report, in the case of the Abel test as good as, and in the case of the 136°—140° C. test better than the results obtained with the same sample before storage with water.

No. 30. Prolonged exposure to a smaller amount of water in daylight, at ordinary temperature. 10 g. of TNA with 4 g. of water were left for 33 days, then washed and filtered. The filtrate showed 0·054% of acid. 10 g. of TNA which had been shaken with water for a few minutes, then washed, gave 0·03% of acid (*cf.* No. 27).

No. 31. Prolonged exposure to excess of moisture in partial daylight. TNA as used in test No. 8, but with 10% of water and an unusually large amount of sulphuric acid remaining after perfunctory washing in the plant, was left in a stoppered amber bottle, on an open shelf, for 35 months. When dried thereafter—without any previous washing—its melting point, when compared, by simultaneous heating, with that of a sample of the same material which had been carefully washed and dried a few days after manufacture, as well as its appearance (colour etc.) were found to be unchanged.

No. 32. *Solubility of TNA in water.* One g. of finely divided TNA was shaken for ½ hr. with 100 c.c. of water at 13° C. in order to remove traces of mineral acid and soluble impurities introduced by the factory water-wash. The material was filtered, washed, and then left for two hours in one litre of water, with frequent shaking. After filtering the water was evaporated at 100° C., a little ammonia having been added to retain all transformation products. The solubility was thus found to be approximately 1:50,000 at 13° C.

Even in solution TNA does not react with water as readily as appears to be commonly supposed[19]:

No. 33. 20 g. of TNA was dissolved in 225 c.c. of acetone at about 30° C., filtered, and stirred into 400 c.c. of water at ordinary temperature. About 90% of the TNA was thus recovered; the rest remained in the mixed solvent, also unchanged, since, even after an hour, the solution gave no nitrous acid reaction with potassium iodide test paper.

No. 34. *Hygroscopicity.* This has been given[20] as 0·12% for a material made on a small scale. This figure approximately holds good for the standard ("green") commercial material. A sample which had been plant-dried to 0·49% of moisture was completely laboratory-dried at 95° C., and then exposed to moist air until its weight became constant, when it was found to contain 0·13% of moisture. A more finely divided ("yellow") TNA became constant after 32 days, with 0·19% of moisture.

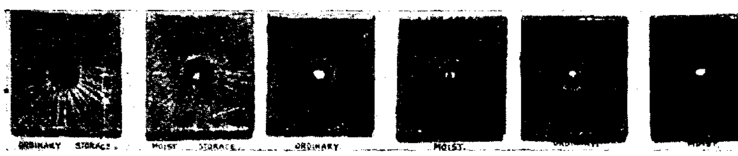
No. 35. *Storage of TNA in detonators.* The detonators were manufactured with 0·3 g. of 80% fulminate and 0·4 g. of TNA per detonator, at a pressure of 176 lb.

Ten weeks' ordinary moist storage (80% saturation):—

(Gain in weight calculated on original weight.)

Week.	Gain in wt. (g.).	Lead block, c.c.	Week.	Gain in wt. (g.).	Lead block, c.c.
1st	0·0015	13·0	6th	0·0030	12·8
2nd	0·0019	12·9	7th	0·0030	12·6
3rd	0·0021	12·85	8th	0·0030	12·6
4th	0·0035	13·0	9th	0·0030	12·6
5th	0·0025	12·9	10th	0·0030	12·6

The keeping qualities of TNA detonators when exposed to moisture at ordinary temperature are thus quite satisfactory. This was confirmed by lead-plate tests carried out on No. 6 detonators, after a year's ordinary and a year's hot-moist storage at 40° C., as shown by the accompanying illustrations.



Fulminate alone. Fulminate-TNA. Lead azide-TNA.

J.—Consideration of tests Nos. 1 *to* 35 *in relation to each other and to the behaviour of other nitro-explosives with a mobile nitro-group* [*tetryl, nitroglycerin* (*nitroglycol*), *nitrocellulose* (*nitrostarch*)].

According to the bulk of expert opinion (*cf.* Guttmann,[21] Nathan,[21] Thomson,[21], Reid,[21] Cullen,[21] Aspinwall,[22] Spica,[23] Barthelemy,[24] Sy,[25] Lenze,[26] Escales,[27] Will[28]), the Abel heat test records, in the first place, not the degree of stability, but the degree of purity of an explosive. When a given impurity is known to lower the heat test of a given explosive and at the same time to cause its progressive decomposition, then the Abel test becomes indirectly a measure of the stability of a particular explosive as affected by a particular impurity. It therefore does not necessarily indicate the relative stability of samples of the same explosive contaminated by different impurities; still less does the Abel test claim, to quote Cullen,[29] to measure the relative stability of different explosives.

Nevertheless, if it is often impossible to draw definite conclusions from a bad Abel test, a good test, provided that no foreign substance which would mask oxides of nitrogen is present, necessarily indicates a corresponding degree of stability; moreover, the Abel tests usually obtainable from good commercial grades of various explosives enable certain conclusions to be drawn as to their relative stability if the effect of impurities normally present on both the test and the stability is taken into consideration.

According to test No. 1, Van Duin and Van Lennep obtained a TNA which would evolve rather less than 0·01% of NO_2 in 115 years at 32° C. (89° F.) and in 37 years at 50° C. (122° F.).[30] In the preparation of this sample potassium nitrate and

[19] Test No. 33 proves that Van Duin (Rec. Trav. Chim., 1917, **37**, 117; 1920, **39**, 150) is mistaken when he makes water responsible for the instantaneous reaction of TNA with sodium acetate in aqueous acetone at ordinary temperature which had been previously described by the present author. Besides, numerous other basic reagents react similarly in the total absence of water.

[29] *Loc. cit.*

[30] These authors (see also Van Duin and Van Lennep, Rec. Trav. Chim., 1917, **37**, 114; Van Duin and Brackmann, Chem. Weekbl., 1919, **16**, 501) and also Stettbacher, base on these results, and on these alone, their allegation that TNA shows "rapid decomposition." Obviously they failed to realise the quantitative meaning of their tests.

acetic acid had been used, both of which lower the heat test of TNA and are never employed in its manufacture. It is therefore not surprising that, on a commercial scale and without any purification other than water-washing, a TNA is obtained which, when properly dried on a plant scale, gives still better results, such as the official tests No. 2.

Nos. 2 and 3 show the effect of moisture on the Abel test. Attention had already been called[31] to the fact that TNA—which, as evidenced by Nos. 21, 25, 30, and 31 and the official tests No. 26 to 29 and 22 is not affected by moisture under any conditions arising during its manufacture, storage, and use—at more elevated temperatures slowly reacts with water[32] according to the equation:

$$C_6H(NO_2)_4(NH_2)+H_2O= C_6H(NO_2)_3(OH)(NH_2)+HNO_2,$$

producing the trace of nitrous acid required to colour the test paper. If at the ordinary temperature the action of even large amounts of water becomes immeasurably small, this must be ascribed not alone to the temperature coefficient of this reaction itself, but to its product with the temperature coefficient of the solubility of TNA in water, which solubility, at the ordinary temperature, is practically nil (see No. 32).

That the quality of TNA does not suffer by the action of moisture during the heat test (No. 2) is due to the fact that the permanent product of the reaction, aminopicric acid, does not affect the stability of TNA (Nos. 12 and 13).

The gas evolution tests at 120° C. are in good agreement with the loss of weight at 130° C., for a perature coefficient[33] of about 2 for 5° C. Tests No. 3 prove that the gas contains only traces of nitrogen oxides (initially about ½%). These include nitrous and nitric acids occluded in the crystals and NO_2 produced by the action of water vapour derived from the decomposition of oxalic acid, and their gradual elimination causes the rate of evolution of NO_2 to fall off (*cf.* No. 3, *f* and *g*, and, for elimination of occluded NO_2 by storage, No. 2, *c* and *d*), until it finally reaches a figure—exceedingly small even at 130° C., and too small for observation at 65·5° C.—representing the actual decomposition of TNA.[34]

Where even traces of occluded impurities, such as certain acids, lower the stability, as with tetryl,[35] the gas evolution increases with the size of the crystals[35]; conversely, actual decomposition of a pure material appears to decrease with increasing size of crystals.[36] Tests Nos. 5 and 6, and 12 and 13, prove that the initial gas evolution of commercial TNA remains unaffected by the size of the crystals. On the other hand, the evolution of NO_2 is higher for ground than for ordinary TNA, even after the effect of steam from oxalic acid decomposition has been practically eliminated by 22 hours' pre-heating at 130° C. Both these facts, again, are explained when the bulk of the initial evolution of total gas is ascribed to removal of an impurity—oxalic acid—which, like aminopicric (*cf.* Nos. 12 and 13) or sulphuric acid, does not affect the stability of TNA. In the following table, the gas evolution from TNA and other explosives containing a mobile nitro or nitrate group is compared:—

	Total gas at 120° C. (c.c. per g. per hr.).			NO_2 at 120° C. (mg. per g. per hr.) 1st 8 hrs.	Effect of product of hydrolysis on gas evolution.
	First 2 hrs.	First 40 hrs.	100th to 200th hour.		
TNA (unrecryst., commercial)	0·425	0·080	0·005[37]	about 0·0007	5% aminopicric acid no effect.
Tetryl (unrecryst., comm.)	0·07	>0·135	—	—	—
„ (recryst., British Service)	0·020[38]	0·022[38]	0·75[35]	about 0·01[39]	10% picric acid causes 14% initial increase.[35]
Guncotton (good quality, Brit. Service)	—	0·366[40]	—	about 0·01 aver.[40]	—
Nitroglycerin[41]	—	3·65[41]	—	5[42]	—
Amatol (50% crude TNT, 50% pure ammonium nitrate)	—	0·015[43]	—	—	—

gas composition of equal volumes of water vapour, carbon monoxide and dioxide (see below), weighing about 1⅓ mg. per c.c. at 0° C. and 760 mm., a temperature coefficient of approximately 2 per 5° C., and corresponding stages of the evolution. The same temperature coefficient is obtained when gas evolution tests Nos. 4 and 7 are compared with each other (*i.e.*, practically the same evolution at 100° C. in first 32 hours as at 120° C. in first 2 hours). There is always a relatively substantial initial evolution or loss of weight, indicating the removal of traces of an impurity, followed by a smaller evolution at a decreasing rate. The impurity is very probably oxalic acid, for the following reasons: The quantitative course of TNA nitrations indicates the formation of substantial amounts of oxalic acid, which is only sparingly soluble in strong sulphuric acid. When nitration is carried out increasingly under conditions (which are well known) causing decomposition of oxalic acid, catalysed by sulphuric acid, the apparent colour of TNA (before drying) changes from yellow to greenish, the occlusion (see under II.) in the crystals decreases, and their gas evolution and loss of weight decrease. Oxalic acid, catalysed by traces of sulphuric acid, is known to decompose into carbon monoxide and dioxide and water at the temperatures of the tests, and with the above tem-

The NO_2 figures explain the difficulty in obtaining a commercial tetryl which will give as good an Abel test as TNA, even after recrystallisation; also the fact that TNA does not evolve brown fumes at 135° C. in 60 hours, whereas good American tetryl was found to do so in 40—60 minutes—thus indicating inferior stability even after allowing for the fifty-fold increase caused by the liquid state[44]

[31] Flürscheim, Z. ges. Schiess- u. Spreng., 1913, **8**, 185.
[32] Whether the same is mixed with the TNA, or derived from the wet test paper.

[33] *Cf.* Bredig, Z. Elektrochem., 1906, **12**, 459.
[34] The approximate accuracy of calculations, by Robertson and Smart's formula, of very low NO_2 concentrations from Abel tests is evidenced, for instance, by the good agreement of figures thus calculated for guncotton at 71° C. with Robertson and Napper's actual determinations of NO_2 at 135° C. (J. Chem. Soc., 1907, **91**, 769), taking Robertson's temperature coefficient of 1·9 for 5°.

[37] Calculated from gas evolution at 140° C., as loss of weight tests at 130° C. include traces of volatile solid matter which count where decrease is small.
[38] Figures obtained by different observers with different regular Service samples.
[39] Calculated from Farmer's test at 125° C. (*loc. cit.*).
[40] From figures by Robertson (*loc. cit.*); Robertson and Napper, J. Chem. Soc., 1907, **91**, 783.
[41] The NO_2 evolution of NG can be calculated for ordinary temperature by Robertson's temperature coefficient (2·2 for 5° C.). In view of this and the comparatively enormous decomposition of NG at 120° C., Stettbacher's remark (Schweiz. Chem.-Zeit., 1919, **1**, 95) that NG, while less stable than TNA at 70° C., was more stable at ordinary temperature, is absurd. Van Duin's (Rec., 1919, **39**, 163) corresponding reference to the absence of acidity in Sobrero's preserved sample of NG overlooks the precautions taken to remove acidity.

[44] Farmer, J. Chem. Soc., 1920, **117**, 1603.

of tetryl at 135° C. The above tests, moreover, afford support for the proposals of the International Commission on Unification of Explosives, Barthelemy, Lenze, and others, to use a storage-fume test at more or less elevated temperatures as the standard stability test, since loss of weight, gas evolution, and trace tests alone are seen to be misleading unless the nature of the change is taken into consideration. Taken in conjunction with a fume test, however, the other stability tests bring out the following crucial fact concerning the relative stability of TNA, with its mobile nitro-group attached to an aromatic ring carbon atom, compared with explosives containing a mobile nitro-group attached to oxygen—such as nitrocellulose, nitroglycerin, or nitrostarch—or to nitrogen, *e.g.*, tetryl:—*Whereas with TNA traces of certain impurities, which are either normally present or else produced in some conditions by the mobile nitro-group, may affect the Abel test, but do not affect the stability, with nitrocellulose, nitroglycerin, tetryl,[45] etc., they generally affect both the test and the stability.* TNA is accordingly intrinsically more stable than any of these materials, and this becomes particularly obvious when old industrial products, and not specially purified samples,[46] are compared.

"Instability" (*i.e.*, tendency to intramolecular, spontaneous decomposition) must not be confounded with "reactivity" (*i.e.*, tendency to inter-molecular reaction with other substances). Thus the reactivity of a nitro-group contiguous to two other nitro-groups—which obtains in TNA—is also to be found in 2.3.4-trinitrotoluene, but less in 3.4.6-, and still less in 2.4.6-trinitrotoluene. Notwithstanding this, Farmer [47] found the gas evolution to be no greater for the 2.3.4- than for the 2.4.6-, and less than for the 3.4.6-compound.

Even reactivity depends essentially on solubility, and the practical insolubility of TNA in water at usual temperatures, together with the lack of autocatalysis by impurities, no doubt largely accounts for the fact that, during periods of storage of TNA, with its own moisture,[48] ranging from 7 to 17 years, no change either in appearance, composition, or melting point has been observed, even with the first samples—some of which were acid or otherwise impure.

K.—Resistance to light.

No. 36. Samples of TNA of varying preparation and purity have been exposed to daylight in ordinary glass bottles on open shelves for periods ranging from 7 to 17 years. In no case has there been any change in appearance or otherwise. Certain other explosives, *e.g.*, nitroglycerin,[49] hexanitrodiphenylamine,[50] and TNT,[51] are, on the other hand, affected by daylight.

[45] Farmer, *loc. cit.*

[46] Farmer (*loc. cit.*) states: "On account of the instability of the nitro-amino group, this compound (tetryl) . . . may undergo deterioration on storage if not completely purified."

[47] J. Chem. Soc., 1920, **117**, 1442.

[48] In actual practice, whether used in blasting cartridges, fuses, shells, bombs, torpedo heads, or elsewhere, the material will necessarily be stored in the dark and in a compressed or cast form. As shown by the tests on exposure to water, moist behaviour to metals, etc., there is in such conditions no change, even with loose material offering a large surface of reaction, and with moisture in excess of the 0·12–0·2% normally present.

[49] Compare Gody, "Matières Explosives" (1907).

[50] Carter, Z. ges. Schiess- u. Spreng., 1913, **8**, 251.

[51] *Cf.*, *e.g.*, Molinari and Quartieri, Z. ges. Schiess- u. Spreng., 1913, **8**, 405, 432. Even the purest TNT is turned green by daylight, a change which is, no doubt, analogous to the photochemical transformation of *o*-nitrotoluene to *o*-nitrosobenzoic acid. This reaction as well as the condensations of *o*- and *p*-nitrotoluenes to stilbenes, etc., and some new observations to be published later, may be attributed to tautomerism (in analogy with the author's bridge formula for primary and secondary nitro-groups; J. prakt. Chem., 1902, **66**, 161, 329):

$$C_6H_4{<}^{NO_2}_{CH_3} \rightleftarrows C_6H_4{<}^{N{<}^{OH}_{O}}_{CH_2}$$

[52] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

L.—Resistance to fire.

The flash point of TNA had been found[52] by a British firm of explosives manufacturers to be 220° C., compared with 186° C. for tetryl. The temperatures of explosion of 247°—237° C. (corr.) for TNA and 196°—187° C. (corr.) for tetryl have since been given by Van Duin and Van Lennep.[53]

No. 37. Some experience is now available on the effect of fire on large quantities of TNA. Once a fire, caused by a diphenylamine autoclave, extended to large vats in which about 16,000 lb. (dry weight) of TNA containing 20 to 25% of moisture was stored. Though the terrific heat of the burning TNA twisted the steel girders of the building into almost unrecognisable shapes, the TNA merely flashed, but did not explode.

No. 38. Later, a TNA packing room was, in the absence of the workers, set on fire by a time fuse; several thousand pounds of dry TNA, nailed down in cases ready for shipment, again flashed without explosion.

M.—Resistance to shock.

Comparative drop-weight tests are not always reliable,[54] and the results previously given[55] have not been confirmed. Later experience proves that TNA is slightly more sensitive than picric acid, and slightly less sensitive than tetryl. Thus, under strictly comparable conditions, the relative insensitiveness to mechanical shock is expressed by the figures:—

	TNT.	Picric acid.	TNA.	Tetryl.
No. 39 (Van Duin and Van Lennep)[56]:				
2kg., maximum height in cm. for no detonation out of 6	–	< 60	< 60	< 60
Minimum height in cm. for 6 detonations out of 6 ..	–	< 60	54·5	52
No. 40 (R. Robertson)[57]: Relative figures	115	100	86	70

In view of these results, which agree with general experience, the impression conveyed by J. Marshall[58] (of the Du Pont Powder Company) that TNA was slightly more sensitive to shock than tetryl is obviously incorrect.

No. 41. A. P. Howell's[59] pendulum friction tests afford a comparison with some other explosives:—

Steel shoe (with 44 lb. added.) 1·5 m. swing.		Steel shoe (with 44 lb. added.)	TNA.		NG-dynamite 40%	
			Tested.	Passed.	Tested.	Passed.
Passed TNT, etc.	Failed Tetryl. TNA. 50/50 Amato.	1·0 m. Swing.	1	0	1	0
		0·5 m. Swing	1	1	1	0
		2 m. Swing (with aloxite cloth)	1	1		

No. 42. Admixture of very little paraffin reduces the sensitiveness of TNA to mechanical shock below that of TNT; *e.g.*, with 5% of paraffin uniformly distributed throughout the material, with 2 kg.,[56] the maximum height for no detonation in 5 out of 5 for TNA was 7 in., TNT 11 in., and TNA 95%, paraffin 5%, 28 in.

[53] Rec. Trav. Chim., 1920, **39**, 170.

[54] Compare R. Robertson, J. Chem. Soc., 1921, **119**, 16.

[55] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[56] Rec. Trav. Chim., 1920, **39**, 174. Van Duin's assertion (with K. Brackmann, Chem. Weekblad, 1919, **16**, 501) that tetranitro-compounds, while stronger, are more sensitive to shock than tetryl, is thus, as regards TNA, disproved by his own results.

[57] J. Chem. Soc., 1921, **119**, 18.

[58] J. Ind. Eng. Chem., 1920, **12**, 336.

[59] U.S. Bureau of Mines, Tech. Paper 234, 1919.

No. 43. The Trauzl block "strength" of TNA is not much reduced by such mixtures with 5% or less of paraffin, but is materially affected by 10% of paraffin; *e.g.*, the Trauzl block net expansion (c.c. per 10 g.) of pure TNT was 216, TNA 315, TNA with 5% paraffin 285 and 295, and with 10% paraffin 205 and 225.

No. 44. Six-pdr. projectiles loaded with a mixture of 95% TNA, 5% paraffin (Mixture "B"), were fired through a 2¼ in. steel plate: the respective weights were 6·05 and 5·94 lb., and the striking velocities 2381 and 2382 f.s. In each case the impact was normal and the projectile penetrated the plate. In the first case the projectile was recovered whole and undeformed, the burster charge remaining entirely inert. In the second case the projectile was recovered broken transversely, in two pieces just forward of the band score. Here again the bursting charge remained entirely inert.

No. 45. Shell fragmentation obtained with above mixture. The report says:—"4-in. Common projectile 1. Weight empty, with base and fuze 28·82 lb. Bursting charge, 2·03 lb. Mixture "B" (tamped) plus 63 g. loose TNA as a booster. Standard 8 dynamite cap and Bickford fuze fitted through fuze plug. Recovered 276 fragments weighing 11·66 lb. Weight of largest fragment 2·9 lb. (base plug); smallest fragment less than 2 grains. Average weight of fragment 0·042 lb. Calculated number of fragments 663." In these tests the material was only hand-tamped, otherwise a substantially higher loading density would be obtained.

No. 46. *Behaviour of TNA towards concussion by an explosive wave.* 5000 lb. of TNA, packed in open cases, was stored in a magazine of galvanised iron, protected by an earth barricade. A packing room a few yards beyond the barricade was blown up, leading to an explosion of about 800 lb. of dry TNA, which precipitated a rock on a railroad cutting about five miles away, partially demolished the barricade, warped the magazine, and threw about the TNA cases, but the 5000 lb. of TNA remained intact. It may be added that, as far as the author is aware, this is the only explosion of TNA which has so far occurred in a TNA plant. It was attributed by the authorities to sabotage.

IV.—Physiological Properties.

TNA shares with nitrocellulose (nitrostarch etc.) the distinction of having no injurious effect on the health of operators or users. It is well known that other nitro-explosives[61] either affect the internal organs, notably TNT[62] before it is completely purified, NG,[63] picric acid,[64] tetryl[65]; or else the skin, *e.g.*, hexanitrodiphenylamine,[66] trinitroanisol.[67]

V.—Power and Sensitising Properties.

The outstanding feature of TNA is its enormous shattering power or brisance (B), which results from its combining a high velocity of detonation (v) with great density (d) and great energy (E), as expressed by Herlin's[68] formula:—$B = E.d^{1+K}.v^{K}$, wherein K is a constant. The energy E or "strength," measured by the pressure of the explosion gases, is proportional[69] to the volume of the explosion gases, per gram of explosive, at the temperature of explosion and at atmospheric pressure.

No. 47. In the following table, column V gives the relative Trauzl block expansions of a number of explosives. They have been referred to tetryl = 375 c.c. by means of Kast's[70] graphical reducing method for elimination of the excess of expansion due to progressive weakening of the block, the reduced figures being given in col. IV; col. VII contains the corresponding reduced Trauzl block figures calculated for equal volumes (6 c.c.) at maximum densities.

[60] The figures of Nos. 39 and 42 again show that only drop-weight tests carried out under identical conditions are comparable.

[72] Temperature for tetryl calculated by Kast should lead to the higher of the two temperatures given for TNA.
[73] Kast, *loc. cit.*
[74] G.P. 260,571.
[75] This relative figure for TNT is, according to the author's experience, generally obtained with a No. 8 detonator, and about 0·255 with a No. 6. TNA and tetryl are little affected by the size of the primer.
[76] According to pressure gauge results obtained by Crawshaw (J. Franklin Inst., 1919, **189**, 607) the "strength" of hexanitrodiphenylamine would exceed that of tetryl by 4·5%. This is not only contrary to general experience, but theoretically impossible.
[77] Bichel, "Testing Explosives," Table III.; value referred to TNT.
[78] Escales, "Schiessbaumwolle."

As to the relative "strength" of nitroglycerin as such, the available data are contradictory. According to the calculations of Waller,[79] by Mallard and Le Chatelier's formula, the "strength" of NG, with an explosion temperature of 3158° C., would be only 332, compared with 395 for TNA; the same proportion would follow from Hofwimmer and Haeckel's[80] calculations for blasting gelatin. The specific heat of gases above 2000° C. is, however, uncertain; accordingly, Kast[81] calculates an explosion temperature of 4250° C. for NG, and 3370° C. for tetryl, which would give relative "strengths" of NG and TNA of about 447 and 427. Comey and Holmes[82] found the ballistic pendulum recoil for 6·15 g. of blasting gelatin and 10 g. of TNT to be identical (=1·62:1), corresponding to a ratio of "strength" for NG and TNT of about 1·53:1; Kast's Trauzl block figures, reduced by his graphical method,[83] give the—incorrect (see note [84])—ratio 1·58:1 for NG:TNT, and Bichel's[85] "Druckmesser" pressures for blasting gelatin and TNT (1·46:1) about 1·4:1 for NG:TNT. On the other hand, the ratio of TNA:TNT, according to Waller's theoretical figures, would be 1·55:1; according to average Trauzl block effects, reduced by Kast's method,[86] 1·4:1; and by comparative pendulum swings[87] 1·46:1. The ratio of the "strength" of NG to that of TNA therefore lies between the limits 0·95:1 and 1·1:1.

Concerning the relative "strength" of the amatols, Crawshaw[88] gave the maximum theoretical pressures, when detonated in their own volume, at 1·6 density, as 10,978 kg. per sq. cm. for an 85/15 amatol, 9851 for TNA, and 9486 for tetryl. Quite apart from the general inaccuracy of "Druckmesser" determinations,[89] Crawshaw had to use a "booster" of 24 g. of tetryl to detonate the amatol, deducting from the result the pressure given by the "booster" alone. He overlooked the fact that the mixture of an amatol with excess of oxygen, and tetryl with a deficit, must give a pressure substantially in excess of the added pressures of the ingredients. Crawshaw's figures are, moreover, theoretically impossible. Not even the gas volume of an 80/20 amatol,[90] with its almost ideal oxygen balance, could produce Crawshaw's relative pressures, even if its temperature of explosion were not very much lower than that of TNA due to its somewhat lower heat of explosion and the composition of its gases (about 60% of which, as compared with about 20% for TNA, are water vapour and carbon dioxide with a high average specific heat). Thus Waller[91] gives for an 78·73/21·27 amatol the temperature of explosion as 2310° C. (TNA=3238°), and its pressure ("strength") as 8·2622 (TNA=10·55).[92]

Not only is an 85/15 amatol substantially weaker than TNA at equal pressures, but there is also little to be gained by comparing relative theoretical pressures, up to 1·6 density, of an amatol which Crawshaw could only detonate with a booster, even at a density of 1·02 (with a theoretical pressure, even based on his figures, of only 7000 kg. per sq. cm.), with an explosive like TNA which can be detonated by an ordinary cap up to its maximum density (with a theoretical pressure, again according to Crawshaw, of about 11,500 kg. per sq. cm.).

As to the relative "strength" of tetryl, its inferiority to TNA by about 10%, as measured in the ballistic pendulum,[93] agrees with Waller's theoretical and experimental figures and with innumerable—partly official—Trauzl block tests. It is therefore obvious that the pendulum results of Cope,[94] recording for NG: TNA: tetryl: TNT the pressure ratios 14:12·1:12·1:10, cannot be correct.

Thus taking equal weights, the energy (E) of TNA approaches that of NG, and exceeds the energy of other explosives. For equal volumes[95] at maximum densities it exceeds all explosives. For its maximum density (d) (see under II) surpasses that of NG (1·6) by about 18%.

For its velocity of detonation (v in the brisance formula) no accurate comparative figure at equal densities are at the moment available, but it has been definitely established that it would exceed those of tetryl or nitroglycerin[96] by several hundred metres per second at equal densities, and exceeds them still more at maximum densities. *In consequence the "brisance" of TNA is not reached by an equal weight, and still less by an equal volume at high density, of any other explosive.*

TNA. Tetryl.

No. 48. The following photographs, obtained by Stettbacher,[97] illustrate the superiority as regards brisance of TNA over tetryl when 3 g. of each were detonated on iron plates 3 mm. thick. Elsewhere[98] Stettbacher states that TNA in respect of its velocity of detonation far surpasses all other nitro-compounds, that the difference between its brisance and that of TNT is perhaps as great as between TNT and dinitronaphthalene; the difference between its brisance and that of tetryl at least as great as between tetryl and TNT; and that its explosive properties undoubtedly surpass those of all other explosives.

No. 49. An idea of the comparative brisance of TNA and TNT is conveyed by the following test:—A bar of wrought iron 5 in. wide, ½ in. thick, was laid on steel supports 15½ in. apart. A paper cartridge containing 100 g. of TNA, or TNT, was

[79] *loc. cit.*

[81] *loc. cit.*

[82] Comm. 8th Int. Cong. Appl. Chem., 1912, **25**, 217.

[83] *loc. cit.* His reduced figures for NG and TNT (485 and 280) are erroneous and should, by his own diagram, read "435" and "275."

[84] The ratio of the "strength" of NG, blasting gelatin, etc., to that of solid explosives, as found in the Trauzl block, is invariably too high. For solid explosives are tested as loose powders, with a low rate of detonation (about 5000 m. per sec. for aromatic high explosives at a density of 1·0) corresponding to the low density of loading; the results are comparable with each other, but not with nitroglycerin, which is tested at a density of 1·6, with a rate of detonation of above 7000 m. per sec.; such a large difference in the rate of detonation results in an additional enlargement of the cavity.

[88] J. Franklin Inst., 1919, **189**, 607.

[89] Comey and Holmes, *loc. cit.*; this is further confirmed by Crawshaw's exceedingly inaccurate value for hexanitrodiphenylamine (see above).

[90] *Cf.* Robertson, J. Chem. Soc., 1921, **119**, 25.

[91] *loc. cit.*

[92] An American 80% ammonium nitrate explosive, tested in the ballistic mortar by Comey and Holmes (*loc. cit.*), was found to possess 73% of the strength of blasting gelatin; it is therefore about equal to 75% guhr dynamite.

[93] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[94] J. Ind. Eng. Chem., 1920, 12, 870.

[95] Waller (*loc. cit.*) says: "The volume of the charge chamber in which explosives are compared in the field is practically a constant, whether it is a borehole or a war head. It would therefore seem more rational to compare explosives in the laboratory by volume." To do this, the above relative "strength" figures must be multiplied by 1·86 to 1·90 for TNA, by 1·5 to about 1·75 for the other explosives, and from the "efficiency" values thus calculated, the "brisance" maxima are obtained by taking velocities of detonation at these maximum densities.

[96] This refers to the higher rate of detonation of NG (>7000 m./sec.). It has also a lower rate (<2500 m./sec.) (*cf.* Comey, 7th Int. Cong. Appl. Chem., **3**, B, 28).

[97] Schweiz. Chem.-Zeit., 1919, **1**, 96.

[98] Z. ges. Scheiss- u. Spreng., 1916, **11**, 112; 1918, **13**, 22

laid crosswise on the bar, midway between the supports, and detonated by a No. 8 cap. TNA tore the iron over a width of 4¾ in. out of 5 in. and folded it completely together. TNT merely bent it to the extent of 7¼ in. in the centre without tearing it.

No. 50. *Comparative brisance of TNA and TNT transmitted through water.* Cartridges composed of varying quantities of TNA and TNT were suspended under water at varying distances from submerged drums made of 1/10 in. steel strengthened by two ribs. In one series of tests, with 1 oz. at 1 ft. distance from a drum 42¾ in. long and 28¾ in. diam., with TNT the indentation produced was 20 in. wide, 13 in. high, and 3 in. greatest depth, but no rib was crushed and a hole was blown on the near side only. With TNA the indentation was 26×21½×5¼ in., one rib was crushed, and holes were blown on both near and far sides.

No. 51. *Comparative brisance in bombs and grenades.* Mills grenades containing 1 oz. each of TNA and other service explosives (tetryl, TNT, etc.) were placed in a wooden box filled with sawdust and suspended from the ceiling of a wooden shed, and detonated to obtain comparative fragmentation. With TNA alone the experiment miscarried, as the floor of the shed was blown through.

No. 52. Brisance tested on steel plates 7×120×120 mm., with paper cartridges containing 100 g. of TNA. With the cartridge standing upright a hole was cut clean through. With the cartridge lying lengthwise across the steel plate (which was supported at both ends), the plate was folded completely together. With the steel plate half protruding over the edge of a steel table, with the cartridge lying on the plate parallel to edge of table, just balanced so that a slight touch would cause it to fall to the ground, the plate was cut completely in two.

Tests such as No. 50 have a direct bearing on the efficiency of charges for depth bombs, mines, and especially torpedoes.[99] In torpedo heads the density is of additional importance,[100] as the volume can only be increased at great expense, also because for equal weights the centre of explosion is brought closer to the object to be destroyed.[101] Wet guncotton is in this respect even inferior to TNT.[102] The amatols under water are also stated to be inferior to TNT, no doubt owing to their low rate of detonation.[103]

Brisance as evidenced by tests Nos. 48, 49, 51, and 52 is all-important for surface demolition, and particularly again when weight or volume is limited, *e.g.*, by the carrying capacity of bombing aircraft,[104] by the calibre of guns used against fortifications, or by the feasible weight of grenades thrown against tanks.

The brisance of TNA, combined with its sensitiveness to detonation by primers, can also be utilised to explode other materials, by employing it either as an intermediate detonator, or else as a sensitiser admixed to such materials.

No. 53. Sensitiveness to detonation by fulminate. Tests by Storm and Cope,[105] 0·4 g. of each nitro-compound per test:—

	Priming charge.		Minimum wt. of primary charge for complete detonation.	
	Fulminate %	Chlorate %	Slightly hand-tamped partially confined.	Compressed at 200 atm., entirely confined.

TNT 0·4g.	100	0	>1·0	0·2600
	90	10	>1·0	0·2500
	80	20	>1·0	0·2400

It is the last column (compression and confinement) which corresponds to practical conditions in detonators and fuses. J. Marshall[106] (of the Du Pont Co.) misquotes the results (for fulminate-chlorate) as tetryl=0·2000, TNT=0·2500, and TNA=0·2000 (which latter should be 0·1700 as actually recorded).

No. 54. The Dynamit-A.-G. Nobel, of Hamburg, record[107] that tetryl and TNA both "when they are compressed to their highest density, retain their property of facility to detonate by means of the initial impulse of fulminate of mercury," and point out that friction under firing strain, which may lead to detonation of the primer in a shell fuse containing an incompletely compressed intermediate charge, is thereby avoided.

No. 55. Sensitiveness of larger quantities of compressed and confined TNA to fulminate.

Paper cartridges containing 100 g. of TNA and 1 g. or ½ g. of fulminate each gave two complete detonations in two tests, while with ¼ g. of fulminate three tests gave one complete detonation and two ignitions.

No. 56. Sensitiveness of wet TNA to an initial impulse. Using a No. 6 detonator, 50 g. of TNA with 0·55% moisture gave compression of lead block 16·32 mm.; with 5·79% moisture 16·06 mm.; no compression was observed with 10·06% and 15·06% moisture, the TNA failing to detonate.

The following results were obtained using No. 6 detonator and primer of dry TNA:—

Wt. of dry primer.	TNA.	Moisture. %	Comp. of lead block, mm.
5·0	45	15·06	17·38
1·0	49	15·06	16·44
0·75	49·29	15·06	None
1·0	49	15·90	15·14
1·0	49	16·42	None
5·0	45	16·42	None

No. 57. Comparative power developed by different explosives when detonated by fulminate alone, and by TNA primed with fulminate:—

Explosive.	Detonator.	Lead block test. (c.c. enlargement/g.)			Ballistic pendulum test. (Net ft. lb./10g.)

[103] For rate of detonation *cf.* Robertson, J. Chem. Soc., 1921, **119**, 27.

[104] TNA bombs used in the war have been described in *Illus. London News* (Dec. 26, 1914) (charge of TNA alone), and by Colver "High Explosives," 1918) (charge of 2 parts of TNT and 1 part of TNA). In either case the violence of the explosion is emphasised

[105] U.S. Bureau of Mines, Tech. Paper 125, 1916.

[106] J. Ind. Eng. Chem., 1920, **12**, 336.

[107] E.P. 2407/1912.

The fulminate detonator contained 1·0 g. of fulminate charge, and the TNA detonator 0·3 g. of fulminate charge, the remainder having been replaced by about half its weight of TNA. Similar results were obtained when No. 7 or No. 8 detonators were used. Thus fulminate, acting through TNA, has a higher initiating effect than a fulminate charge heavier than both of these together when employed alone.

No. 58. Relative power developed by TNT shell charges exploded by TNA- and tetryl-intermediate detonators. The conclusion was reached by the officer in charge that "the action of TNA was not inferior and was even superior to the action of commercial tetryl, which is the regular explosive for detonators of the type mentioned."

As to the sensitising properties of TNA when used as an ingredient in explosive compositions, several tests have already been recorded.[108] Substantial progress has since been made, and a few further tests will now be described.

No. 59. Sensitising and pressure effects of TNA when mixed with TNT.

(*a*) TNT-TNA composition, cast, then ground (TNT solidif. p. 77° C.). With TNT alone the enlargement with a No. 6 cap in Trauzl block (average of 4 tests) was 228·75 c.c.; TNT with 9% TNA 239·25 c.c.; TNT with 20% TNA 264·75 c.c.

(*b*) TNT-TNA mixtures, not cast (TNT=m.p. 77° C.). With No. 6 cap (5 tests each), TNT alone gave average 235·0 c.c.; with 10% TNA 246·8 c.c. Using No. 8 cap (3 tests each) TNT 275·0 c.c.; TNT with 10% TNA 290·7 c.c.

(*c*) TNT-TNA mixtures, not cast (standard pure TNT). Using No. 6 cap TNT alone gave 228 and 190 c.c.; TNT with 5% TNA 208 and 217 c.c. Using No. 8 cap TNT alone gave 237, 250, and 174(?) c.c.; TNT with 5% TNA gave 256, 255, 245 c.c.

No. 60. Sensitising and pressure effects of TNA when cast with dinitrobenzol (DNB), then ground:—Pure TNT gave an enlagement (Trauzl block) 230 c.c.; TNA 25%, DNB 75%, 221 c.c.; TNA 33%, DNB 67%, 240 c.c.; TNA 40%, DNB 60%, 255 c.c.; TNA 50%, DNB 50%, 277 c.c.

No. 61. Sensitising and brisance effect of TNA when cast with dinitrobenzol in shells.

6-pdr. shells, loaded with a cast composition of 3 parts of dinitrobenzol and 1 part of TNA, were fired against steel plate in same conditions and with identical results as given under No. 44. The following fragmentation was obtained in a 4-inch common projectile:—Weight empty with base and fuze plugs 28·80 lb. Bursting charge 2·7 lb. Mixture "A" (cast) plus 63 g. loose TNA as a booster. Standard 8 dynamite cap and Bickford fuze fitted through fuze plug. Recovered 400 fragments weighing 9·65 lb. Weight of largest fragment 2·16 lb. (base plug), smallest less than 2 grains. Average weight of fragments 0·024 lb. Calculated number of fragments 1161.

No. 62. Sensitising effect of TNA on TNT in detonating fuses. It has already been recorded[109] that, in equal conditions, an admixture of 20% of TNA increases the velocity of detonation of a 2·6-mm. TNT detonating fuse by 12%.

Nitroglycerin (or dinitroglycol) and TNA appear to be the only materials with which it is commercially[110] possible to sensitise cheap ingredients so as to obtain powerful explosives of high density, good oxygen balance, and a high rate of detonation.

[108] Z. ges. Schiess- u. Spreng., 1913, 8, 186.
[109] *loc. cit.*
[110] Tetryl has also been proposed for this purpose, for instance in "Fortex" with ammonium nitrate (Mem. Poudres et Salp., 1913-14, 128), but its brisance is not such as to compensate for its high cost of manufacture.

No. 63. *Types of industrial TNA explosives.*

(1) Dry. (*a*) Substituting TNA for TNT etc. to obtain higher density without loss of sensitiveness and thereby reduced hygroscopicity and higher power. Examples: TNA 35%,[111] ammonium nitrate 65% (compressed to 1·6 sp. gr.); TNA 50%,[111] barium nitrate 40%, potassium nitrate 10% (compressed to 1·8 sp. gr., no packing required). (*b*) Substituting TNA plus cheap and comparatively inert ingredients for TNT etc. Example: TNA:Dinitrobenzol (1:3) 12%[111]; ammonium nitrate 88%. (*c*) Adding TNA to black powder.

(2) Plastic. (*a*) Substituting TNA plus a liquid or semi-liquid material for NG in dynamites to increase power by reducing amount of inert material necessary for oxygen balance; to achieve greater safety in manufacture, transportation, and use, avoid risks from exudation,[112] volatility,[113] or freezing, and prevent deterioration on storage[114] or through warm climates. Example: TNA 35%, liquid nitrated solvent naphtha (about 14% N) 5%, nitrocellulose 0·2%, combustible matter 2·2%, sodium nitrate 57·6%. The pressure, velocity of detonation, and sensitiveness of this explosive were found to be close to those of a corresponding 40% NG-dynamite. (*b*) Sensitising cheap plastic compositions by means of TNA, to obtain increased power and reliable detonation[115] at increased densities. Examples: TNA 20%, liquid nitrated solvent naphtha (14% N) 9·7%, nitrocellulose 0·3%, barium nitrate 70%. This gave good detonation with No. 8; it was not tested with No. 6 detonator.

%

Detonation with No. 8 detonator	good	good	good	not taken	not taken
Detonation with No. 6 detonator	good	fair	fair	not taken	not taken
Small block compression (No. 7 detonators) (75 g. explosive)	13·18 mm.	not taken	not taken	12·0 mm.	13·12 mm.

Mixtures of TNA, liquid nitrated toluols, and a chlorate or perchlorate in varying proportions may be used according to nature of chlorate selected and degree of nitration of the toluol.

It appears remarkable that the enormous brisance of TNA can be reduced to such an extent as to

[111] Some comparative tests carried out with these explosives have been described in Z. ges. Schiess- u. Spreng., 1913, 8, 185.
[112] To which sodium and ammonium nitrate dynamites are particularly liable (*cf.* Marshall, "Explosives," 2nd ed., p. 363).
[113] Which leads to "the severe and nauseating headaches and other disagreeable and dangerous maladies which result from the handling of explosives containing nitroglycerin" mentioned in U.S.P. 1,309,553 by Swint (du Pont Powder Co.).
[114] Thus gelatinised dynamites suffer on storage in warm climates, blasting gelatin quickly becomes difficult to detonate and loses in power, sodium nitrate gelignite cartridges are particularly liable to remain unexploded after storage, and NG has a tendency to revert to its lower rate of detonation, and large consignments of such explosives have to be condemned from time to time (*cf.* Marshall, "Explosives," 2nd ed., p. 368; Kast, Z. ges. Schiess- u. Spreng., 1913, 8, 89, 175; Stettbacher, *ibid.*, 1918, 13, 405; Hargreaves, J., 1914, 337; Mann and Kirton, Report to Govt of West Australia, J., 1919, 848A).
[115] Thus potassium and still more sodium chlorate explosives are generally difficult to detonate even at moderate densities; sodium and ammonium nitrate and sodium chlorate explosives give the more trouble through insensitiveness due to hygroscopicity, the less compressed they are; plastic nitrostarch (*cf.* Swint, *loc. cit.*) and nitrated solvent naphtha explosives and other plastic non-NG explosives (*cf.* Schweizer, Z. ges. Schiess- u. Spreng., 1919, 14, 25) generally tend to be too insensitive, and TNT as a sensitiser is insufficiently active and cannot be used in sufficient proportions on account of its great oxygen deficiency (*cf.* U.S.P. 1,357,764, Cook and Harris, Atlas Powder C.).

permit of large proportions of the same being embodied in propellants for fire-arms.

No. 64. The following is an example of a composition which gave the required velocity *within the permissible pressure*, when fired with a 150-g. bullet in a 0·3 Service rifle:—

60 parts of finely ground TNA was embodied with 40 parts of soluble nitrocellulose by means of 92 parts (by weight) of pure ethyl acetate,[116] and worked into powder of 0·0602 in. diam. by 0·2185 in. length.

Charge.	Initial velocity. ft. per sec.	Pressure. lb. per sq. in.
42 grains	2523	46,750
43·5 "	2593	47,400
44 "	2647	52,100

The weight, and still more the volume, of such a charge are substantially less than for a corresponding nitrocellulose powder charge. These tests have only been preliminary, and it is not yet possible to state either the maximum velocity obtainable within the permissible pressure, by further changes of composition and dimensions of the powder, or the nature of stabilisers, if any, which may possibly be required.

VI.—Notes on the Manufacture of TNA.

Experience has shown the nitration of *m*-nitraniline to TNA to be an exceedingly safe operation, and it has all along been carried out as an ordinary chemical—not an explosive—manufacture. This is due to the great solubility of *m*-nitraniline in sulphuric acid, which excludes any formation of separate layers, such as may occur with mixed acid and toluene or nitrotoluenes; also to the high melting point of TNA, which causes it to be obtained as a finely divided, crystalline suspension in the spent acid (which cannot be detonated even after filtration), and thus prevents—unlike TNT—the formation of separate layers of explosive and spent acid; perhaps also to the relatively low temperature of nitration, though according to tests on an experimental plant scale the temperature may be allowed to rise uncontrolled without danger of explosion; and, lastly, to the fact that the nitration is a single-stage operation, and can therefore easily be made fool-proof.

The nitration has hitherto been carried out in units up to about 2500 American gallons capacity. The control has been found so easy that there is no objection to the use of even larger units. The time occupied by a nitration has been reduced to about 6 hours. After separation from the undiluted spent acid by filtration the TNA is water-washed and again filtered. It is then ready for drying. With 20% of water content it cannot be detonated by any method (*cf.* No. 56), and is admitted on the U.S. railroads as a non-explosive.

The drying of TNA corresponds to the drying of picric acid, *i.e.*, it is relatively safe. Several methods have been employed, but drying on shelves, by means of hot air fans, has given the best results.

The latest operating results indicate the following net consumption of materials, per lb. of TNA produced, including all intermediate stages (dinitrobenzol and *m*-nitraniline): Benzene 0·6 lb., sulphuric acid (100% basis, including 5% reconcentration loss) 2·3, nitric acid (100%) 1·0, sodium sulphide (60%) 1·0, sulphur (lumps) 0·4 to 0·5 lb. About 1·7 lb. of sodium thiosulphate can be recovered, but has hitherto been run to waste. The above sulphuric acid consumption can be substantially reduced where the high—and superfluous—heat test requirements for military TNA are waived, also where the reconcentration loss of the relatively large amounts of sulphuric acid used is avoided by mixing the spent acid directly with fresh acid for nitric stills. This has been found possible in actual practice, since the spent acid retains neither explosive nor volatile organic matter, and since it is recovered undiluted.

Starting from a reasonably pure *m*-nitraniline, the yield previously given for the final stage (130—140 parts of TNA per 100 parts of *m*-nitraniline)[117] has been confirmed on plant scale.[118]

Conclusions.

In 1913, on the basis of results obtained on an experimental scale, it was stated[119] that TNA possesses valuable properties in a high degree; that it is a well-characterised crystalline chemical compound, neutral, without action on metals; that it is the strongest solid explosive,[120] has a higher density than any other purely organic explosive, is non-hygroscopic, does not change on storage, is specially resistant to heat and friction, not over-sensitive to mechanical shock, can be easily detonated by an ordinary detonator even when highly compressed, has a smaller oxygen deficiency than other aromatic explosives, that it is a very suitable ingredient of explosive mixtures, and can be made at a competitive price.

All of these conclusions have been confirmed by later developments on an industrial scale. In addition, it has been proved that TNA is not injurious to health, and that it does not change through moisture, during manufacture, storage, or use—such change requiring more or less prolonged exposure to a combination of moisture and temperature which both substantially exceed the normal, whereas in practice, where temperature may exceed the normal (in shells, bombs, etc.), moisture does not, and where moisture may be high (in submarine mines etc.), the temperature is not.

The successful development of the industrial production of TNA has been achieved largely by the skill and perseverance of American technical men and operators.

Fleet, Hampshire.

THE DETERMINATION OF ZINC BY THE POTASSIUM FERROCYANIDE METHOD.

BY E. OLIVIER.

The determination of the zinc content of Australian concentrates is usually carried out volumetrically, either by the so-called American method (the potassium ferrocyanide method) or by the Schaffner method (titration of the ammoniacal

[116] This solvent was selected as it does not react with TNA, whereas alcohol does.

[117] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[118] Van Duin and Van Lennep (Rec. Trav. Chim., 1917, **37**, 114) on the basis of a few laboratory nitrations of aniline and of *m*-nitraniline with potassium nitrate—which are but two of the numerous methods of obtaining TNA described in the author's patents—record somewhat lower yields. In view of the definite examples previously given of nitration temperatures of 100° C. down to below the ordinary (*e.g.*, E.P. 3224 (1910); Z. ges. Schiess- u. Spreng., 1913, **8**, 185), Van Duin and Van Lennep's remark (*loc. cit.*, *cf.* Rintoul, Soc. Chem. Ind., Ann. Repts., 1919, 530) that the author's nitration temperature of 70° C. was too high, is irrelevant; whereas Stettbacher's converse allegation (Z. ges. Schiess- u. Spreng., 1916, **11**, 112) that no nitration occurs below 100° C., is entirely incorrect. Subsequently Stettbacher himself (Schiess- und Sprengstoffe, 1919, 201-2) quotes "Van Duin's (*sic*) method" of nitration at 50° C. as the best. As to the nitration of *m*-nitroacetanilide, attention had already been called (Flürscheim, G.P. 243,079) to an intermediate compound characterised by its pale yellow needles which had been obtained by Witt and Witte (Ber., 1908, **41**, 3091) when using two equivalents of potassium nitrate and operating in certain conditions, which they found on analysis to be a new isomeride of picramide. Van Duin and Van Lennep (Rec. Trav. Chim., 1920, **39**, 145), departing in material respects from the indications given by Witt and Witte, were thereby misled into erroneous suppositions which will be dealt with elsewhere, in connexion with a discussion of the purely scientific aspect of the mechanism of these nitrations.

[119] Z. ges. Schiess- u. Spreng., 1913, **8**, 185.

[120] It can now be added that it has a higher shattering power than *any* other explosive

solution with sodium sulphide); this last method is also sometimes termed the Vieille Montagne method (*cf.* Fiévet, Bull. Soc. Chim. Belg., 1919, 28, 351).

In the American method, as usually carried out, the ore or concentrate is decomposed by means of nitric acid and potassium chlorate, the mixture evaporated to dryness, the residue boiled with ammonia and ammonium chloride solution, and the filtrate acidified; the copper is removed by means of lead foil, the liquid is neutralised with ammonia, a solution of potassium hydrogen tartate and ferric chloride is added, the solution heated to about 75° C., and titrated with standard potassium ferrocyanide solution in presence of ammonia until a spot test with acetic acid shows a blue coloration.

The method used for preparing the solution for analysis results in the extraction of the zinc together with the copper, cadmium, calcium, and magnesium, and part of the lead, iron, and manganese. Of these elements only the zinc, copper, cadmium, and manganese are precipitated by the ferrocyanide, and only the copper is removed prior to the titration, so that the cadmium and manganese present are returned as zinc. Whilst the amount of cadmium present in the concentrates is usually so small as to be negligible (it averages about 0·1%), this is not so in the case of manganese, which may be present to the extent of considerably more than 1% and so result in a high figure being returned for zinc. In one case, for example, the author found 1·16% of manganese (as Mn_3O_4) in the zinc solution before titration.

That amounts of manganese such as are found in concentrates vitiate the titration is shown by experiments in which manganese corresponding to 2% and 4% respectively of Mn_3O_4 was added to solutions of known zinc content; on titration of these solutions 0·8% and 2·3% or zinc in excess of the quantity present was indicated.

To separate the manganese completely from the solution, a few c.c. of hydrogen peroxide are added to the mixture of ammonium chloride solution and ammonia used to treat the residue resulting from the decomposition of the ore; this renders the manganese insoluble, and the results obtained agree closely with those found by the Schaffner method.

When the percentage of manganese present is small (*e.g.*, 0·25%) the results obtained by the two methods (without the use of hydrogen peroxide) agree within about 0·1%, but in most cases manganese will be present in amounts sufficiently great to necessitate the use of hydrogen peroxide.

The American method has another disadvantage, especially where a large number of titrations have to be made daily—viz., the titration is carried out in hot solutions; this is necessary in order to obtain complete precipitation of the zinc ferrocyanide in a dense, gelatinous form. Further, the blue coloration produced in the spot test is not entirely satisfactory, since although the reaction is very sensitive the colour is not always very distinct in presence of coloured ferrocyanides and the intensity of the colour is not appreciably increased with increasing amounts of potassium ferrocyanide.

In the author's opinion, the Schaffner method is preferable to the American method in view of the above facts, and also having in mind the fact that the zinc is precipitated as colourless sulphide, which affords a ready indication of its freedom from other metallic sulphides. The only other colourless insoluble sulphide known is the double sulphide of zinc and cadmium, discovered by the author in 1886, but the error arising from this source is negligible since, as already pointed out, zinc ores contain very little cadmium, and moreover the greater part of the cadmium is separated as sulphide together with the lead and copper.

Central Laboratory of the Vieille Montagne.

Glasgow Section.

Meeting held at Glasgow on April 22, 1921.

MR. J. H. YOUNG IN THE CHAIR.

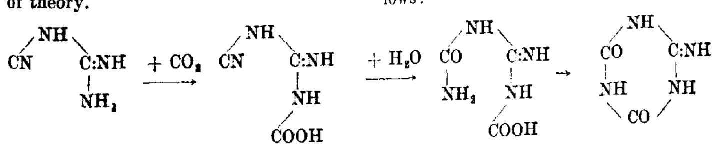
THE PREPARATION OF GUANIDINE SALTS AND OF NITROGUANIDINE.

BY THOMAS EWAN, M.SC., PH.D., F.I.C., AND JOHN H. YOUNG, M.SC., F.I.C.

The methods described in this paper for the preparation of guanidine salts and nitroguanidine easily and economically were worked out between 1903 and 1905. At that time the authors thought they saw a possibility of utilising guanidine nitrate and nitroguanidine industrially.

The possibility of preparing guanidine salts from cyanamide was first investigated. Erlenmeyer (Annalen, 1868, **146**, 253) obtained guanidine from cyanamide and ammonium chloride in alcoholic solution at 100° C. Volhard (J. prakt. Chem., 1874, [2], **9**, 15) heated aqueous cyanamide and ammonium thiocyanate at 100° C. (10 hrs.) and obtained some guanidine thiocyanate. In these papers no mention of yield is made.

The authors first investigated the formation of guanidine nitrate from sodium cyanamide (Na_2CN_2), a sample containing 72·8% Na_2CN_2 being used; 5 g. of this was dissolved in 200 c.c. of cold water and concentrated nitric acid added drop by drop as the cyanamide was dissolving so as to keep the solution as nearly neutral as possible, and finally made just acid to methyl orange with one drop of $N/1$ nitric acid. The solution, containing cyanamide and sodium nitrate, was evaporated on the water-bath to a small bulk and transferred to a large test tube; 5 g. of solid ammonium nitrate was added and the whole heated in a sulphuric acid bath to 145°—150° C., and kept at this temperature for about one hour, during which time the liquid evaporated considerably and became pasty, but there was no appreciable disappearance of cyanamide. The temperature was then slightly raised and a little more (1 g.) ammonium nitrate added. At 155° C. the mass began to froth considerably and cyanamide slowly disappeared, and after a further ½ hr. none was left. The product was dissolved in hot water, filtered from a little insoluble matter, and the guanidine determined as picrate. The yield was 43·1% of theory.



Vozarik's method (Z. angew Chem., 1902, **15**, 670; J., 1902, 1041) was employed to determine guanidine quantitatively. A quantity of the substance containing about 0·25 g. of guanidine compound is dissolved in 25 c.c. of water (filtered if necessary), precipitated with 75—125 c.c. of 0·8% ammonium picrate solution (made by dissolving 3·75 g. of picric acid in water, adding ammonia till alkaline and making up to 500 c.c.), and after standing for 1—2 hrs., filtered through a known weight of asbestos in a Gooch crucible, washed twice each time with 12 c.c. of ammonium picrate solution, drained well on the pump and dried at 100° C. to constant weight; 1% of the weight of the precipitate and 2·5% of the weight of asbestos is allowed for ammonium picrate retained, and the solubility of guanidine picrate in ammonium picrate solution is taken as 1 in 4000.

A number of preparations of guanidine nitrate, starting with sodium cyanamide, were made with yields usually near 50% theory. The operation may be divided into the following stages:—(1) Dissolving the sodium cyanamide in dilute nitric acid to form a solution neutral to methyl orange and containing cyanamide and sodium nitrate. (2) Evaporation of this solution to dryness in the water-bath under reduced pressure (50 mm.). (3) Extracting the cyanamide from the residue by digesting with ether. (4) Evaporation of the ethereal solution. (5) Heating the residue with excess of solid ammonium nitrate to 150°—180° C. to form guanidine nitrate.

In one experiment the amount of cyanamide at the end of stages (1) to (4) was determined and the quantity of guanidine nitrate at the end of (5). The following were the yields at the respective stages expressed as percentages of the theoretical yield: (1), 100; (2) and (3), 97·9; (4), 95·2; (5), 57·3%. From the above results it appears that the loss of yield takes place in stage (5), so it was decided to polymerise the cyanamide at the end of stage (4) by adding a few drops of ammonia and warming; when this was done the subsequent stage (5) gave an almost theoretical conversion of dicyanodiamide into guanidine nitrate according to the equation $H_4C_2N_4 + 2NH_4NO_3 = 2CN_3H_5.HNO_3$.

This led the authors to investigate more fully the formation of guanidine salts from dicyanodiamide.

B. Rathke (Ber., 1885, **18**, 3102) found that dicyanodiamide heated with ammonium chloride and water at 150° C. gives considerable quantities of guanidine hydrochloride; ammonia and carbon dioxide are also produced and react with dicyanodiamide to form biguanide and melanurenic acid respectively.

$$NH_2.C(:NH)NH.CN + NH_3 = \underset{\text{Biguanide}}{NH_2.C(:NH).NH.C(:NH).NH_2}$$

$$NH_2.C(:NH).NH.CN + CO_2 = NH_2.C(:NH).NH.CO.N:CO$$
$$= \underset{\text{Melanurenic acid}}{NH{<}\begin{matrix}C(:NH).NH\\CO\text{——}NH\end{matrix}{>}CO}$$

G. Bamberger (Ber., 1883, **16**, 1074) observed the formation of melanurenic acid from dicyanodiamide and water at 160°—170° C. and later (Ber., 1890, **23**, 1856) he formulated the change as follows:—

Smolka and Friedreich (Monatsh., 1888, **9**, 1227) obtained biguanide from the product of the interaction of alcoholic dicyanodiamide and ammonium chloride at 105° C. (8 hrs.), and have also (Monatsh., 1889, **10**, 86) described experiments in which small quantities of dicyanodiamide and ammonium chloride (1 mol.) or sulphate (½ mol.) were heated together in the dry state at 160°—170° C. The products of the reactions were biguanide salts. The melt, when dissolved in water and treated with copper sulphate and sodium hydroxide, gave a rose-red precipitate of biguanide copper sulphate $(C_2N_5H_6)_2Cu,H_2SO_4$.

Bamberger and Dieckmann (Ber., 1892, **25**, 543) say that the formation of biguanide by this method

is a very delicate operation, temperature, proportion of reactants, and time affecting the result. They recommend that an intimate mixture, quite dry, of 5 g. of dicyanodiamide and 8 g. of ammonium chloride be heated in an oil bath, with constant stirring, until the temperature reaches 195° C., at which point it is kept for 5—10 mins. and then cooled, extracted with water, filtered from a little insoluble matter (ammelin), and the copper salt precipitated; the yield of copper salt was 45—50% of theory.

Bamberger and Dieckmann also state that Smolka and Friedreich's temperature (160°—170° C.) is too low, and that at 195° C. biguanide decomposes into ammelin. The authors examined Bamberger and Dieckmann's method and concluded that the proportions given (5:8) were due to a printers' error (5:3 is more nearly correct). The following results were obtained:—

Dicyanodiamide. g.	NH_4Cl. g.	Final temp. ° C.	Time to heat up, mins.	Time at top temp., mins.	Copper biguanide sulphate dried at 100° C., g.	Yield % theory.
5	8	190-200	—	6	0·08	0·7
5	3	190-200	—	6½	0·8	7·3
5	3·2	195	—	5½	0·8	7·3
5	3·2	195	—	10	0·42	3·8
5	3·2	185	5	5	1·57	14·3
5	3·2	175	5	5	1·88	17·1
5	3·2	165	2	5	2·00	18·2

It will thus be seen that most of the investigators mentioned above considered a biguanide salt to be the principal product resulting from heating a mixture of dicyanodiamide and an ammonium salt. Where the formation of a guanidine salt was stated no mention of yield was made, and the fact that very high yields can be obtained seems to have been quite overlooked. The authors prepared the following guanidine salts, viz., nitrate, thiocyanate, sulphate, and chloride, by heating mixtures of dicyanodiamide with the respective ammonium salts in the manner described below. In the case of the nitrate and thiocyanate almost theoretical yields were obtained, whilst in the case of the less fusible sulphate and chloride the yields were not quite so high, but nevertheless satisfactory. One of these salts (thiocyanate) was made later in the same way, and a very satisfactory yield obtained by Werner and Bell (Chem. Soc. Trans., 1920, **117**, 1133), who found that by heating an intimate mixture of 43·5 g. of dicyanodiamide (95·5%) and 76 g. of ammonium thiocyanate to 120° C. for 3½—4½ hrs. guanidine thiocyanate is formed, and a yield of 90·8% of theory was obtained.

Guanidine nitrate.—The following method was found to be satisfactory. The proportions used were according to the equation

$$H_4C_2N_4+2NH_4NO_3=2CN_3H_5,HNO_3.$$

A mixture of 300 g. of dicyanodiamide and 576 g. of ammonium nitrate was heated in an enamelled iron pan, 10 in. diameter and 6 in. deep, by means of a Bunsen flame, and stirred with a thermometer. The mass was all fused at 110° C. and was heated to 150° C., at which point the burner was removed as the heat of the reaction kept the temperature up for some time. The mass became more viscous as guanidine formed. As soon as the temperature began to fall the burner was replaced till the temperature reached 160° C., when the reaction usually gives out sufficient heat to increase the temperature of the mass to 180°—190° C., at which point the reaction is soon completed. Finally it was heated to 200° C. for about 10 minutes and poured into iron moulds. 90—95% of guanidine nitrate was obtained in this way. The time of the complete operation was about 1¼ hrs.

Larger batches were made in the following way:—3 kg. of ordinary commercial ammonium nitrate was melted in an enamelled iron pan 12 in. diam. and 6 in. deep over a Bunsen flame and some 20—30% of the dicyanodiamide theoretically required (say 1·5 kg.) added during the fusion in order to lower the melting point; the remainder was added gradually at 160° C. at such a rate that no external heat was required to keep the temperature steady at this point. When all the dicyanodiamide had been added the mass began to crystallise, so the temperature was raised to 170° C. The mass became liquid again but soon solidified, so the temperature was raised to 180° and finally to 190° C., waiting each time till the mass was pasty. Finally it was heated to 200° C. and poured into moulds. The product contained 91% of guanidine nitrate and the loss of weight was about 3%. 3 hrs. was required for an operation. About 170 lb. of guanidine nitrate was made in this way.

Guanidine thiocyanate, CN_3H_5,HSCN, was made in a similar way to the nitrate by heating an intimate mixture of 55 parts of dicyanodiamide and 100 parts of ammonium thiocyanate. Yields of over 90% were easily obtained.

Guanidine sulphate, $(CN_3H_5)_2,H_2SO_4$. When the ammonium salt is not readily fusible it is more intimately mixed with the whole or a considerable part of the dicyanodiamide before being heated. For example, 100 parts of dry ammonium sulphate is ground together with 60—62 parts of dicyanodiamide (or a considerable part of it) and the mixture fused in an open vessel. The fused mass (to which any dicyanodiamide remaining unmixed is added gradually) is then maintained at a temperature preferably between 150° and 180° C. until it has solidified to a cake of guanidine sulphate. In one experiment 125 g. of an intimate mixture of equal molecules of dicyanodiamide and ammonium sulphate was heated. At 140°—145° C. the product caked together and gave off ammonia; at 157° C. it was semi-fused, and became at 165° C. a thick paste, considerable heat being evolved. At 177° C. it was quite fluid and frothed a good deal, and the temperature was maintained without external heat. The mass was kept at 170°—180° for ½ hour. 111 g. of product was obtained containing 5·67% insoluble in water (ammelin), 1·16% of biguanide sulphate, 93·7% of guanidine sulphate, and a trace of melamine. This represents a yield of guanidine sulphate of 83% of theory.

Guanidine hydrochloride, CN_3H_5,HCl, was made in a similar way to the sulphate from 100 parts of ammonium chloride and 80 parts of dicyanodiamide.

Nitroguanidine, $CN_4H_4.NO_2$, was prepared by J. Thiele (Annalen, 1892, **270**, 1) by treating 100 g. of guanidine nitrate with a cold mixture of 100 c.c. of concentrated sulphuric acid, 50 c.c. of sulphuric acid containing 10% of SO_3, and 40—50 c.c. of nitric acid (sp. gr. 1·5) and pouring into 2 litres of water after a few minutes. The yield does not seem to be mentioned.

The authors prepared nitroguanidine from guanidine nitrate in three ways, viz., by the action of: (*a*) sulphuric acid alone, (*b*) nitric acid alone, (*c*) a mixture of sulphuric and nitric acids.

Method (*a*).—The solubility of nitroguanidine in dilute sulphuric acid was first determined; 1 g. of powdered nitroguanidine was mixed with a definite quantity of water and concentrated sulphuric acid (sp. gr 1·84, 82%, 1 c.c. contains 1·69 g. H_2SO_4 and 0·15 g. water) added, drop by drop, till the nitroguanidine had just dissolved. The temperature of

the saturated solution was 13° C. The following results were obtained:—

% H_2SO_4 in final acid.	Solubility of nitroguanidine, g. in 100 g. acid.	g. Nitroguanidine dissolved for each g. H_2SO_4 in the acid.
33·2	2·55	0·077
28·2	1·37	0·049
25·2	0·95	0·038
22·7	0·87	0·038
20·0	0·72	0·036
17·2	0·65	0·037
5·8	0·37	0·064

The sulphuric acid should therefore be diluted so as to make the final acid 20%; 4% of the nitroguanidine should remain in solution for each g. of H_2SO_4 used per g. of nitroguanidine.

To examine the action of sulphuric acid on guanidine nitrate the materials used were 92% acid as above, and Nordhausen acid (1 c.c. weighs 1·9 g. and contains 62·23% H_2SO_4 and 33·77% SO_3). The guanidine nitrate used was crystallised from dilute nitric acid and was colourless and practically pure. Nordhausen acid acts too violently on guanidine nitrate; it also appears to decompose nitroguanidine. In one experiment the nitroguanidine dissolved in concentrated sulphuric acid decomposed suddenly, with evolution of much heat and gas, on adding a little sulphuric anhydride to it.

In the following experiments the temperature never exceeded 30°—40° C.; a little gas is evolved in the warm mixtures—none if the temperature is kept at 12° or 13° C.—but the yield appears to be hardly affected. The mixture was always poured (after standing for a definite time) into sufficient water to dilute the sulphuric acid to 20%. The nitroguanidine which separated was filtered on the pump, washed once with a little cold water, drained well, dried, and weighed.

The action of different quantities and strengths of sulphuric acid on guanidine nitrate, also different times were considered systematically. In experiments using 5 g. of guanidine nitrate and 16·9 g. of acid the highest yields (79·1% in 30 mins., 79·6% in 18 hrs.) were obtained with acid containing 92% of H_2SO_4, although almost equally good yields (77·7—78%) were obtained for both times with 87% or 95% acid. Using 5 g. of guanidine nitrate and 25·4 g. of acid for 48 hrs., the highest yield (75·1%) was found with 87·1% acid; with a smaller quantity of acid (8·45 g.) the best yield (84·5% in 48 hrs.) was obtained with 95·5% acid, but yields of over 80% resulted when 92% or 100% acid was used. With 10 g. of guanidine nitrate and 8·45 g. of acid the yields were low in all cases, the best results (36·8% in 22 hrs. and 40·5% in 72 hrs.) being obtained with acid of 102·4% H_2SO_4.

To ascertain the effect of temperature on the reaction, 5 g. of guanidine nitrate was dissolved in 10 c.c. of 92% sulphuric acid, without cooling, and placed in a water-bath at 81° C. rising to 84° C. 7 mins. after mixing much gas was being evolved from the acid liquor. The product was poured into water and let stand overnight before filtering etc. Yield 3·03 g.=71·1% theory.

To try whether the nitroguanidine separated completely in a few minutes when poured into water, 5 g. of guanidine nitrate was mixed with 10 c.c. of 92% sulphuric acid, allowed to stand for 25 mins., poured into 65 c.c. of water, allowed to stand for 18 hrs., filtered, washed, dried, etc.; yield 3·35 g.=78·7% theory, which is practically identical with the yield got by filtering at once after pouring into water.

The time allowed for reaction of 5 g. of guanidine nitrate in 5 c.c. of 92% acid appears to influence the yield considerably; *e.g.*, after 10 mins. the yield was 64·5%; 17½ hrs., 76·5%; 48 hrs., 83·1%. When 5 g. of guanidine nitrate is dissolved in 10 c.c. of 92% acid the time of reaction has little effect; thus after 12 mins. the yield is 78·2%; 25 mins. 78·7%; 30 mins., 79·1%; 3 hrs. 23 mins., 78·2%; 17 hrs. 40 mins., 79·6%.

Method (b).—The solubility of nitroguanidine in nitric acid was determined by dissolving 0·5 g. of nitroguanidine in hot water, cooling to get it finely divided, and adding nitric acid, drop by drop, till the whole was just dissolved in the cold. Results:—

c.c. water.	c.c. conc. HNO_3.	% HNO_3 in final acid.	g. nitroguanidine dissolved by 1 g. HNO_3.
15	4·5	27	0·085
25	6·0	23	0·064
40	7·5	19	0·051
50	7·2	15·5	0·053
100	5·3	6·4	0·073

The minimum solubility thus lies at 19% HNO_3. The concentrated nitric acid used contained 87·6% HNO_3 (1 c.c.=1·3 g. HNO_3 and 0·18 g. H_2O), and was reddish coloured. 10 c.c. weighed 14·814 g. The following results were obtained using 5 g. of nitroguanidine and nitric acid alone for nitration:—18 hrs.: 3 c.c. of acid, yield=0%; 5 c.c., 11·3%; 10 c.c., 15%; 15 c.c., 46·5%. 96 hrs.: 3 c.c., 0%; 5 c.c., 24·4%; 10 c.c., 53·8%; 15 c.c., 64·5%. The mixtures stood at the ordinary temperature. The 5 g. of guanidine nitrate dissolved completely in 15 c.c., almost completely in 10 c.c., very little in 5 c.c., whilst the 3 c.c. was soaked up completely, leaving a solid mass. The 5 c.c. mixture solidified to a mass of prismatic crystals on standing, and several crystals of the same shape came out of the 10 c.c. lot. Apparently guanidine nitrate is capable of combining with another molecule of nitric acid.

Method (c).—Action of mixture of H_2SO_4 and HNO_3 on guanidine nitrate. The following results were obtained, using 5 g. of guanidine nitrate and allowing to stand for 68 hrs:—

HNO_3. %	H_2SO_4. %	H_2O. %	Acid mixture, g.	Yield. %
35·1	50·8	14·1	7·4	11·5
50·0	36·1	13·9	10·4	44·4
38·3	60·6	1·1	6·8	65·7
38·3	60·6	1·1	13·6	70·0

The above results show that method (*a*) is the most satisfactory and that the best yields are obtained by using 5 g. of guanidine nitrate to 5 c.c. of 92%—98% sulphuric acid and standing for 48 hrs., but if time is a consideration very satisfactory yields can be obtained by using 5 g. of guanidine nitrate to 10 c.c. of 87%—95% acid and standing for 30 mins. A batch of about 60 lb. of nitroguanidine was made as follows:—80 lb. of crude guanidine nitrate (90—94%) was dissolved in 147 lb. of 95% sulphuric acid and stirred by hand with an iron rod in a steel ladle, 21 in. diameter and 15 in. deep, set in a wooden tub with cold water flowing. The temperature was kept at 25°—33° C. Six hours was required to get the guanidine nitrate dissolved (this could be reduced by more efficient cooling). The mass was allowed to stand overnight, when it had half solidified; it was diluted with 514 lb. of water in stoneware vessels and the nitroguanidine was filtered on a stoneware vacuum filter. The cake was washed with a little water and then stirred with 100 lb. of water in a stoneware vessel and a portion tested by titrating with $N/1$ sodium carbonate and methyl orange; 2 lb. of sodium

carbonate was added, which made the liquor slightly alkaline. It was filtered off and drained again, then stirred with a further 100 lb. of water, filtered, pressed well down, and finished with a small wash on the filter. The damp product weighed 94 lb. and contained 43% of water. It was dried in an evaporator till a final product was obtained which weighed 55 lb. and contained 6·57% of water and 0·17% of sodium sulphate. Assuming the guanidine nitrate used to be all 94% (which is too high as it was slightly damp), the yield works out at 80·2% of theory.

This work was done in the laboratories of the Cassel Cyanide Co., Ltd., Glasgow, and our thanks are due to the directors for permission to publish the results.

Meeting held at Burlington House on April 4, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THE SCIENTIFIC PRINCIPLES OF COLD STORAGE.

BY PROF. WALTER STILES.

(*Abstract.*)

From the physico-chemical point of view all foods consist of very complex systems. With the exception of butter, the chief constituent of each system is water in which are dissolved various inorganic salts, while organic substances, particularly proteins and fats, are dispersed through the aqueous phase in the form of an emulsion, or in the colloidal condition.

Most foods are capable of preservation in cold storage, and many systems of classification of such substances are possible according to the point of view adopted. When we have to consider the scientific principles involved, the most satisfactory classification is one based on the temperature of storage. From this point of view we can divide all food materials into two classes. In the first class the food material during storage has to be maintained at a temperature above the freezing point of the food on account of serious deterioration which takes place if the water in the food is allowed to separate out as ice. Fruits are very typical of this group of foods. Many other plant organs, such as tubers and roots, behave similarly. Unless it be in very exceptional circumstances, freezing has so far not been applied with success to the preservation of these, and when kept in cold storage care has to be taken that the temperature does not fall below the freezing point. In the second class much lower temperatures are employed, so that it is ensured that the greater part of the water is frozen. As typical of this group of foods may be cited mutton and rabbits.

These two methods differ greatly with regard to the scientific problems involved. In the first case, the physical condition of the food remains unaltered, but various chemical processes, including enzyme actions, take place, which lead to changes in the composition of the food, which are known as maturing or deterioration according as the changes improve the quality of the food or the reverse. At these temperatures of storage also many foods are liable to be attacked by micro-organisms, which in practically all cases lead to unpleasant changes in the food substance. The changes taking place in foods during cold storage at temperatures above the freezing point are thus chemical changes that are to be investigated by the methods of organic chemistry, including biochemistry. In the second case, however, in which the food is preserved in the solid frozen condition, we are faced with an entirely different set of problems. The chemical actions which bring about changes in the composition of the food must proceed with extreme slowness, both on account of the low temperature and because the liquid medium in which such reactions take place is now replaced by a solid one. From the freezing point downwards the quantity of liquid becomes less and less until at the eutectic point the whole mass is completely solid. For the same reasons the growth of micro-organisms is either greatly retarded or completely inhibited. On the other hand, freezing involves a change of state of one of the substances of the food, that is, there is a change in physical structure. Cold storage in the frozen state will only be successful if this change in physical structure which takes place on freezing is reversed on thawing, so that in its final state preparatory to use the system comprising the food is nearly identical with the fresh produce. The problems involved here are problems of physical chemistry; the biochemical problems which figure largely in the storage of food above the freezing point take here only a secondary place, but they are not necessarily negligible, especially if storage is continued over a long time.

There are several advantages in keeping food in the frozen rather than in the physically unchanged state. As the result of the much slower rate of the chemical reactions which produce deterioration, material can be preserved for a considerably longer time frozen than unfrozen. Produce can be packed more closely when frozen and, not being nearly so liable to the attacks of micro-organisms, does not require nearly so much attention and inspection.

One of the main objects of scientific research in cold storage should therefore be to transfer as many substances as possible from the class of substances which cannot be preserved frozen to the class of those which can.

As an example of the first class of foods fruit may be selected. The conditions which allow of variation are the temperature and humidity of the air in the storage chamber, illumination, movement and composition of the air in the store, and the possible protection of the fruit by a wrapper of some sort. The stage of development at which it is best to commence the storage of fruit is obviously a matter of importance, and so is the determination of the length of time which the fruit can be kept in store. For the solution of these problems it is clear that a careful study of the changes taking place during the ripening of fruit is necessary. Moreover, there is no reason to suppose that different species of fruit, or even different varieties of the same fruit, go through the same series of changes, so that it appears probable that every species of fruit will have to form the subject of a separate biochemical examination. Such investigations are now being made, and the results should be of the greatest interest for the student of cold storage. The need for such separate investigations is emphasised when it is remembered that the value of each particular species or variety of fruit depends upon something very characteristic in the flavour or aroma.

Since the rate of the reactions involved in ripening of fruit increases with rise of temperature, it may be concluded that, in general, the nearer the temperature is to freezing point, so long as it is above it, the longer can the fruit be stored, and there has been in practice a continuous tendency to use lower and lower temperatures until at the present time temperatures about 0° C. are often employed. As to other conditions in the store, the

degree of movement of the air and the relative humidity are generally determined by the liability of the fruit to lose water by evaporation, or to be attacked by moulds or bacteria. In the latter case air movement with a comparatively dry atmosphere is indicated; in the former, moist still air is more suitable.

What has been said so far will give some idea of the principles involved in the cold storage of fruit; similar considerations will hold for other food substances stored above the freezing point; even a material such as beef, which is usually preserved in this way, is to be considered as subjected to the same scientific principles. It will not be necessary therefore to consider further instances of food maintained above the freezing point, and we may pass on at once to the principles concerned in the preservation of food in the frozen condition.

It has already been noted that the chief difficulties here arise from the change of state from liquid to solid not being reversed on thawing with sufficient completeness. In substances such as rabbits and mutton, which are generally stored in the frozen condition, this reversal is practically complete; in other cases, as in some fish and in beef, with the ordinary methods of freezing the reversal is anything but complete, and such frozen material on thawing yields material inferior in quality both to fresh produce and to that stored for short periods above the freezing point.

We are at once faced with the question of how systems such as meat and fish behave on freezing. Many observations have been made on somewhat similar systems, such as sols and gels of gelatin. If a gelatin gel with a concentration of, say, 2 to 5% is allowed to freeze in a cold room, ice separates out at a number of centres leaving a more concentrated solution of gelatin. As the ice crystals grow there will thus be left a network of gelatin getting more and more concentrated, enclosing in the network solid ice crystals. On thawing the mass, the water resulting is not re-absorbed by the gelatin to any greater extent than gelatin will normally absorb water at a low temperature. A certain proportion of the water will be re-absorbed, but not by any means the whole of it, and so the original system will not be regained after the freezing and thawing processes. If the block of gelatin is squeezed in the hand, water can be squeezed out of the gelatin as readily as it can be squeezed out of a wet sponge.

The same sort of thing happens when vegetable tissues—at any rate, such things as apples and potatoes—are frozen and thawed, while a similar phenomenon is to be noted in the case of beef. When a quarter of beef frozen in air is cut, there is generally a noticeable separation of liquid from the beef ("drip") whereby valuable nutrient substances may be lost from the meat; it is also possible that the alleged toughness of some frozen beef is connected with this. On the other hand, no such difficulty arises with mutton.

Our main problem is, therefore, can we by any means so alter the method of freezing that the separation out of comparatively large crystals of ice can be prevented? Can we so freeze the tissues that the space relations of the water and other constituents are maintained the same in the frozen as in the unfrozen condition? If this be done, we may then hope that on thawing the original system will be renewed.

As a guide in this matter we have the researches of Tammann on supercooled liquids. By varying the degree and rate of cooling it was shown to be possible to vary within wide limits the texture of the resulting solid. By cooling a liquid slowly to a temperature not far below the freezing point there is a high crystallisation velocity but only a few centres of crystallisation form; hence crystals grow rapidly from a few centres, and so a very coarsely crystalline mass results. Further below the freezing point the number of crystallisation centres increases, so that a finer-grained mass results. Further still below the freezing point the number of crystallisation centres reaches a maximum and at lower temperatures diminishes again until at a certain low temperature the number of crystallisation centres which form in unit time is practically zero. If then the substance is cooled so quickly that it passes rapidly through the temperature interval over which crystallisation centres form at an appreciable rate, the substance should set in a form approximating to an amorphous or glass-like condition as the number of crystallisation centres which form is small, and so is the crystallisation velocity. Working on these principles, Tammann was able to obtain 59 substances out of 153 examined, in the form of a glass, and he expresses the opinion that with sufficiently rapid cooling the majority of substances should be obtainable in this condition.

In the case of a gel or a viscous substance such as the content of the muscle of fish and meat, there is another point of view. The formation of large crystals at a few centres leaving a more concentrated gel forming a network, involves the movement of water molecules through the viscous or jellified mass. This movement requires time. For this reason also rapid cooling of such systems as animal juices should prevent the separation of large ice crystals from the general mass.

These considerations suggest that rapid freezing may solve the difficulty of the separation of the constituents of frozen tissues. A number of experiments carried out on the freezing of complex sol and gel systems at different rates supported this conclusion, while there are a number of records in the literature indicating clearly the efficacy of rapid freezing in preserving the relations of the constituents of complex colloidal and organic systems after freezing and subsequent thawing.

The evidence thus seems clearly to indicate the solution of the problem of storing food in the frozen condition. The next step is to discover means for carrying out the freezing sufficiently rapidly. When only small objects are in question this is not as a rule a difficult matter; lowering the temperature may be sufficient, and for small experiments the low temperature of liquid air can be used without much trouble. But the matter is not so simple when we have to deal with large objects, such as large fish and quarters of beef, since the rate of cooling and freezing at any point in the body depends on its nearness to the surface and on the specific heat and thermal conductivity of the body, as well as on the temperature of the cooling medium.

With differences in these respects we need not be concerned here, as most of the food materials with which we have to deal do not differ much in their specific heat and thermal conductivity from water, 75% or upwards of their substance consisting of that compound. But it is of some importance that the thermal conductivity of ice is about four times as great as that of water, while its specific heat is only about one half. On these accounts ice will cool much more quickly than water, other things being equal. Consequently, the passing over of the outer layers of a cooled mass of meat or fish into the frozen state, so far from hindering the further withdrawal of heat from the inner regions, materially assists it.

In order to bring about rapid freezing various devices are possible. The most obvious is to use a lower temperature. But here the cost of maintaining very low temperatures will probably limit the downward extension of the temperature of the cooling medium beyond a certain limit. Strong agitation of the cooling medium will also aid in the more rapid cooling of objects, owing to the breaking

down of temperature gradients. This means can, however, not effect a very great increase in the freezing velocity. A third variable which influences the rate of cooling is the thermal conductivity of the cooling medium. Cooling curves of pieces of beef and other food substances of the same dimensions frozen in a variety of substances have shown without question how greatly the rate of cooling is influenced by the thermal conductivity. We are in practice limited by two considerations, namely, cost and any injurious action of the cooling medium on the food material. Thus mercury, in spite of its high conductivity, is ruled out altogether as a possibility. Of practicable substances water has a fairly high thermal conductivity, but as it freezes at a higher temperature than the food, it is of no use for the purpose. But salt solutions have much the same thermal conductivity as water, and these can be obtained in liquid form right down to their eutectic points. Thus sodium chloride can be obtained in solution down to a temperature of $-21°$ C., magnesium chloride down to $-33·6°$ C., and calcium chloride down to $-55°$ C. These temperatures are considerably lower than those generally employed for freezing materials in air—the ordinary method—whereas the thermal conductivity is about 28 times as great as that of air.

By the use, then, of lower temperatures or of a salt solution instead of air as the cooling medium, the rate of freezing can be much increased, and by applying these facts it should probably be possible to achieve the cold storage of any food material in the frozen condition. The use of a cooling medium of high conductivity is, however, more effective in the case of smaller objects than with larger ones. For instance, cylinders of 5% gelatin 1 cm. in diameter in brine at $-10°$ C. freeze 13 times as quickly as in air at the same temperature, whereas when the diameter is 25 cm. they only freeze $2\frac{1}{2}$ times as fast. For this reason freezing in brine should be more efficient in the case of fish than of large bodies such as hind-quarters of beef. Many experiments with fish on both a small and large scale, in this country and in Holland and Germany, indicate that freezing fish in sodium chloride brine is highly satisfactory with most species of fish, and the method is probably capable of extension to all species of fish. Penetration of salt into the fish is in most cases negligible and on cooking there is no evident salty flavour; in any case the entrance of salt can be prevented by the use of a protective covering if it is thought necessary.

With beef the problem is not yet completely solved. Small pieces of beef, up to about 6 lb. or so, can be frozen in brine so that there is no sign of separation of liquid after thawing. The elimination of "drip" is then only a question of using a suitable freezing velocity. It may be necessary to use a lower temperature than $-21°$ C., in which case some solution other than sodium chloride brine would have to be employed. The objection to calcium chloride or magnesium chloride is the unpleasant taste of these salts, but some mutton frozen in calcium chloride brine had not the slightest trace of unpleasant flavour on cooking, and some hindquarters of beef frozen in sodium chloride brine at $-20°$ C. showed no sign of "drip" after they were thawed, nor of salty taste when cooked. But here a secondary difficulty presents itself. A large body, such as a hind-quarter of beef, has to remain in brine at $-20°$ C. for from 12 to 24 hours for freezing to be complete to the middle. During this time a considerable quantity of salt enters the surface layers of the tissue, and on thawing the quarter the surface appears to have a dull colour. The meat itself appeared excellent in flavour in the trials made with whole quarters, but the appearance was against it. But the solution of this difficulty should only be a matter of biochemical research, and one may conclude with confidence that to obtain frozen beef of a quality indistinguishable from that of fresh meat is only a matter of time. Whether it will be economically worth while so to preserve this or any other food material is another matter, which does not concern the scientific investigator as such.

Discussion.

The Chairman said that some 25 years ago considerable interest had been shown in the storage of hops in evacuated metal cylinders. The results were satisfactory and comparable with cold storage; it seemed unfortunate that more had not been done in this apparently promising direction.

Dr. G. Schack-Sommer said that some experiments had been made by Charles Tellier, the pioneer of refrigeration, in which meat and fish were subjected to a vacuum to remove the oxygen from the tissue, before placing them in cold storage. Successful results had also been obtained in preserving soft fruit in cold storage by the use of an atmosphere of carbon dioxide to prevent respiration.

Dr. R. T. Colgate asked for information as to the best methods of thawing frozen food. It was stated that frozen eggs should be thawed at quite a low temperature.

Mr. E. Hatschek said that the freezing and thawing of gelatin gels was not a completely reversible process, and he could not see that the rate of freezing or thawing could ever make it so. The swelling of a gel was also materially affected by the electrolytes present in the water, and particularly by hydrogen and hydroxyl ions. If a gel containing an electrolyte was frozen, the water froze out a good deal of the electrolyte also, and that, it seemed to him, was an additional difficulty in getting the process reversible with animal tissues, which contained electrolytes isotonic with 0·7—0·9% NaCl.

Dr. S. Miall asked if the author had had occasion to study the conditions under which minute animals could live through freezing.

Mr. C. J. Tabor said that rabbits could not be kept in cold storage for ten months at a temperature of 8° or 10° F. without damage. Meat could be kept for 6 or 8 months, and chickens about 6 months. One difficulty in the refrigerated produce trade was the elimination of moulds. His own tests had shown that they were harmless, but it was customary to condemn produce carrying mould growths. A rise of about 10° F. in the temperature of the refrigerating apparatus (say from 15° to 25°) was sufficient to start mould growth, although it would not occur if the temperature were kept constant. Once started, a reduction of the temperature did not prevent the growth. The reason for this was that the rise of temperature produced a surface dampness to which the moulds (*Mucor mucedo* and *Penicillium glaucum*) adhered. Another trouble with frozen meats was the yellow discoloration caused by bursting of the fat cells on thawing, whereupon the fat became discoloured and rancid. The freezing of fish always involved loss of flavour; the tissues were more delicate and more readily disrupted by the expansion of their watery contents than in the case of meat. Another form of damage, quite distinct from mould, was "must"; it exhibited no signs of fungoid growth and could not be removed by wiping. Its cause was obscure; beyond a slimy dampness on the goods, and a very disagreeable odour, nothing could be traced; meat so damaged was dangerous to health.

Prof. Stiles, replying to a question by the Chairman, said that butter which had been kept in cold storage at $-10°$ C. for nine months showed no alteration in the fat-soluble vitamins. He was not aware that any experiments had been carried out on the other vitamins. In reply to Dr. Colgate, he

said that German investigators had concluded that if the meat were frozen rapidly enough, so that the space relations were maintained in the frozen condition, it did not matter whether the thawing was rapid or slow. On the other hand, the American, Richardson, advocated slow thawing if freezing had taken place in air, because apparently some of the water that was otherwise lost in the "drip" was re-absorbed if the meat were thawed slowly. All his own experiments had been conducted with the view of trying to get the freezing so rapid that a reversible change on thawing was obtained. He had tried to freeze eggs in brine, but they had always burst. Referring to the freezing of small animals, he said there were references in literature to fish that had been frozen in Lake Superior and lived afterwards, but he did not believe that that fish had ever really been frozen, and he often wondered whether small animals like worms were really frozen. Frogs' muscles, when frozen very rapidly, had been found alive after thawing. Micro-organisms were not always destroyed by freezing; some probably were, but the majority of spores were not, and directly the conditions were suitable for their growth, especially when water condensed on the surface, they would germinate and grow. Fish that had been frozen rapidly in brine was indistinguishable from fresh fish when cooked. Although water expanded on freezing by 10%, this did not burst the tissues. Plant tissue could be frozen, but that did not burst the cells, and the reason why frozen salmon turned rancid was probably connected with the fact that it had been slowly frozen. He doubted if it would turn rancid so soon if it were rapidly frozen.

Meeting held at Burlington House on May 2, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

FRACTIONAL DISTILLATION WITH CONTACT RING STILL-HEADS.

BY R. LESSING, PH.D.

In the discussion following the paper on gas scrubbing towers by Donnan and Masson (J., 1920, 239 T) I drew attention to the advantages of packing absorption towers and distilling columns with contact rings of the type described in my British Patent No. 139,880 (J., 1920, 321 A). These rings, as shown in fig. 1, consist of cylinders of approximately equal height and diameter, having a gap in the circumference and a more or less diametrical partition connected on one side with the cylinder, but out of touch on the opposite side. They are disposed indiscriminately in the tower or column at the angles which they find when dropped promiscuously into the vessel. Packing material of a similar kind but consisting of plain cylinders was devised by Raschig (E.P. 6288 of 1914; J., 1914, 907), and has found extensive application for works purposes of various kinds. The provision of the central partition and openings, however, has been found to increase the efficiency of the packing very considerably by adding to the contact surface available in a given tower space, and by enhancing the drainage capacity of the packing.

The further advantage of greater ease in manufacturing these rings in large numbers has made it possible to provide them also for laboratory purposes in smaller sizes than the standard one used in large scale plants, which is usually 1 in. diameter by 1 in. height.

The 1-in. rings are used in a great variety of plants of the chemical and gas industries, amongst which may be cited ammonia scrubbers, oil scrubbers, absorbers, washers, tar extractors, carbolate decomposers, carbonating and decarbonating towers, debenzolising stills, distilling columns, and still-heads for many substances such as tar and petroleum products, alcohols and essential oils, also condensers, coolers, and heat exchangers. Indeed they are applicable wherever large interfacial surface for liquid and gas or vapour, combined with a minimum of back pressure, is essential.

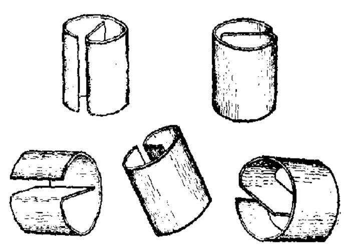

FIG. 1.

The inferiority of laboratory methods to works practice of fractional distillation has been frequently pointed out (*e.g.* Kreis, Annalen, 1884, 224, 259; Silvester, J., 1920, 188 T), and is mainly due to the impossibility of reproducing the factors of time, contact, and distance on the small scale. Since the small rings have been put on the market it has become possible to remedy this deficiency and to use them for the construction of laboratory still-heads on the lines on which the larger ones are applied in manufacturing operations. The early experiments were made mainly with the intention of reproducing as far as possible works conditions in the laboratory, and for this purpose plain tube still-heads as proposed by Hempel were used in which the glass beads were replaced by contact rings ¼ in. × ¼ in. This made it possible to do away with the principal drawback attaching to the Hempel still-head, viz., choking and consequent "puking" caused by the very considerable resistance offered by the glass beads, which usually take up 80% or more of the still-head space. The resistance of a ring-packed column is so small that still-heads of very considerable height can be used. Incidentally the surface offered by this ring packing is a very large one. It amounts to 8250 sq. cm. per litre (251·5 sq. ft. per cb. ft.), whilst the volume occupied is only about 13% of the total space, leaving 87% of the space free for vapour and condensate.

The advantages of such an arrangement are:—Extreme simplicity—the rings are dropped into plain glass tubes and the use of complicated and fragile products of the glass blower's art is avoided; the same charge of rings can be transferred from one still-head to another whatever its dimensions, or can be used for other purposes in absorption towers or reaction vessels, and are therefore of general applicability; they are not lost if the vessel containing them should get broken.

Apart from these advantages, still-heads packed with these rings have been found to possess a fractionating efficiency which is superior to any known laboratory still-heads or dephlegmators of comparable dimensions. The reason for this must be sought firstly in the large surface per unit of volume which affords ample opportunity for condensation of the vapours and re-evaporation of the condensate; secondly, the turbulence created by the frequent deflection of the currents of vapour and condensate, which can only flow in any one direction for a distance of ¼ in. or less. Thus, formation of "cores" and "channelling" is avoided, and the release of vapour trapped in the condensate is promoted by the continual exposure of fresh surfaces.

A not inconsiderable portion of the action is due to surface tension effects of liquid forming films along the points or lines of contact between adjoining rings. These films or pockets are more or less effective seals, to be broken by the ascending vapour current and thus ensuring intimate contact and interchange between liquid and vapour phase. This amounts to a very considerable bubbling effect which is increased or decreased with the rate of drip of condensate. In order to enhance this bubbling effect and also to keep all surfaces well irrigated, it is desirable to induce as much return-flow as is compatible with the drainage capacity of the column and the avoidance of excessive back-pressure. If the still-head is used unlagged, as is done with the majority of "dephlegmators," it acts largely as a reflux condenser with a rapidly decreasing quantity of condensate towards the top. The bubbling therefore diminishes from bottom to top, and the surface effect of the upper portion of the still-head is not utilised to the full extent. For this reason it is preferable to lag the still-head with asbestos, cotton wool, or corrugated cardboard, thereby avoiding premature condensation, and to provide a reflux condenser which allows the required portion of vapour to pass uncondensed and to distil over, whilst the bulk is condensed and returned, copiously wetting the whole length of the still-head.

This reflux condenser need not be worked as a "regulated temperature" still-head (see F. D. Brown, Trans. Chem. Soc., 1880, 37, 49), but merely serves to re-condense that portion of the vapours which it is desired to use for the irrigation of the still-head and not to send over into the receiver. In this connexion it may not be generally known that the ratio of vapour collected as distillate to that returned into the still can be determined calorimetrically by connecting the water outlet of the final condenser with the inlet of the reflux condenser. The ratio of the rise of temperature in the reflux condenser to that in the final condenser indicates directly the proportion of return flow to distillate. By this mode of working the adjustment of the degree of fractionation for a given height of still-head can be effected, at any rate on the large scale, and may also be occasionally of use in the laboratory.

Where long still-heads are used, a water- or oil-cooled reflux condenser can be dispensed with by leaving a short length of the upper end of the tube unlagged, relying on atmospheric cooling.

A still-head packed with rings may, then, be regarded as a scrubber in which the ascending vapours are scrubbed with the descending condensate. All considerations applied to the theory and practice of scrubbing or absorption towers are therefore applicable to still-heads, and their study should yield valuable results if carried out from the scrubbing point of view.

However well a still-head is lagged there is bound to be a certain amount of radiation and gradual drop of temperature from bottom to top. If a sufficiency of scrubbing liquid is to flush the whole length of the column, radiation must be compensated by the sensible and latent heat of the vapours. In cases where the heating of the still would become excessive, or the quantity of material is insufficient, the loss by radiation may be made up by external heating of the still-head—say by means of electric resistance wires. It is also important to pay attention to the specific heat and conductivity of the packing material.

Whilst the drainage capacity of the packing is very high, the rings of necessity retain a thin film of the liquid after draining. On account of the large surface involved this is more than, for instance, in Young's evaporator still-head, which is specially designed to retain a minimum of condensate. This point acquires importance only in cases where very small quantities are fractionated and the distillation of the last fraction is desired. In preparative work or in analysis where large enough quantities are available, this drawback disappears entirely as the error becomes negligible, or may be corrected in many cases by steaming the column and recovering the distillate. The amount retained varies according to the viscosity of the substance, its wetting power for various metals, the physical condition of the rings, and the height of column. For instance, aluminium rings retain after 30 minutes' draining 1—2 c.c. of toluene per 100 c.c. of column space, whilst a retention as low as 0·06 c.c. by the same volume was found for a petroleum spirit after some hours' draining.

The construction of these still-heads is exceedingly simple. Tubes from 2·5 to 4·0 cm. wide and from 40 to 150 cm. long will cover the range of most ordinary requirements. The usual constriction at the bottom for connecting through a cork stopper should be as wide as possible to avoid choking with condensate. The tubes may be fitted with a side-tube at the top when no separate reflux condenser is used, or may have an outlet fixed through the top stopper with or without the interposition of a reflux condenser. In glass tubes as a rule no support for the rings is required. They are merely dropped into the tube in a slanting position; on turning it up the rings will arrange themselves and bridge over the bottom shoulder.

If metal tubes are used, as is the case on a semi-manufacturing scale, wire gauze of as large a mesh as will support the rings should be fixed at the base, and practically the whole cross-section of the tube is then available for the discharge of condensate into the still and the upward current of vapours.

B. Glinsky still-head with three bulbs (3 cm. diam.).
C. Hempel still-head with glass beads (3 cm. diam. × 35 cm. high).
D. Young evaporator still-head. 5 sections. (75 cm. high.)
E. Young and Thomas dephlegmator. 18 sections. (130 cm. high.)
F Lessing contact rings in plain tube (4 cm. diam. × 140 cm. high).

FIG. 2.

In fig. 2 the separating efficiency of a contact ring still-head is compared with that of a number of other still-heads, the classical example of a 1:1 mixture of benzene and toluene being selected. Curves A, B, and C are plotted from values given by Friedrichs (Z. angew. Chem., 1919, 32, 340); D and E are taken from Young's work (Trans. Chem. Soc., 1899, 75, 708). Curve F represents a distillation with a plain

tube still-head 4 cm. wide and 140 cm. high filled with ¼-in. aluminium contact rings, at a rate of 60 drops per minute.

The dimensions of the various still-heads are stated on the graph, and although they are not directly comparable, the almost complete separation is very striking. Benzene and toluene distilled over to the extent of 47% and 48% respectively, each within 1°, leaving only 5% of the total mixture in the middle fraction.

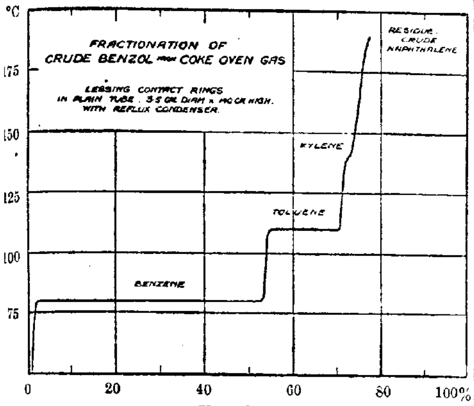

FIG. 3.

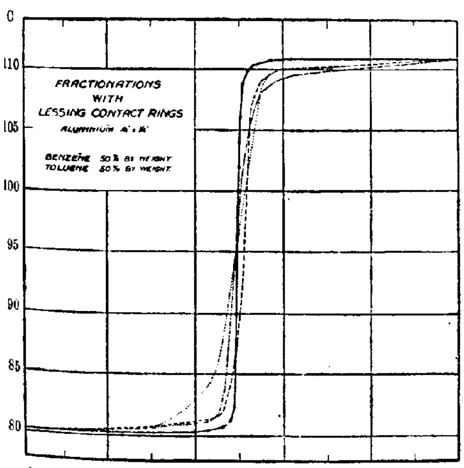
Fig. 3 shows the fractionation of a commercial sample of crude benzol obtained from the washing of coke-oven gas with creosote oil. In this case 2000 c.c. was distilled from a metal still in an oil bath with a ring-filled still-head 3·5 cm. diameter by 140 cm. high. A short reflux condenser was employed. These conditions explain the extreme sharpness of the curve, which even indicates the presence of a small quantity of xylene. The sample contained over 20% of naphthalene and wash-oil, and the residue solidified on cooling.



A. 11. 2·5 cm. diam. × 40 cm. high, lagged with cardboard. Reflux condenser.
B. 7. 3 cm. diam. × 75 cm. high, unlagged.
B. 6. 3 cm. diam. × 75 cm. high, lagged with cardboard except 10 cm. from top.
C. 8. 4 cm. diam. × 140 c.m. high, lagged with asbestos card except 10 cm. from top.

FIG. 4.

In fig. 4 four distillations are plotted in order to show the influence of the still-head dimensions, heat insulation, and reflux condensing. This graph proves clearly that a certain minimum of scrubbing surface is required in order to obtain the best results. Curve C8 is identical with Curve F in fig. 2.

Very interesting results were obtained in the fractional distillation of a commercial fusel oil distillate of sp. gr. 0·840 at 15°/15° C. The results of

Lessing aluminium contact rings in same tube.

FIG. 5.

a preliminary distillation of this sample with a Young 12-pear still-head (fig. 5) show the type of curve obtained by the test customarily employed in many works laboratories.

The following results were obtained on fractionating 1000 c.c. from a glass flask with a glass tube still-head 140 cm. high by 4 cm. wide, filled with ¼-in. copper contact rings and lagged with asbestos cord to within 10 cm. of the top. The exposed portion was covered with corrugated paper during the distillation of the fractions above 100° C. Rate of distillation 5 c.c. per minute. At 130·0° the still-head was replaced by a smaller one 40 cm. high by 2·4 cm. wide, and distillation continued at a rate of 7 c.c. per minute. This change accounts for the loss of 1·4%. Volume of distillate was noted for every rise of 0·2° and plotted in fig. 5.

	Loss ..	—	1·4	—	—

In the preceding table the percentages of fractions as taken off, together with their specific gravities and refractive indices, are recorded.

Fraction I. contains a mixture of aqueous ethyl and *n*-propyl alcohols. The bulk of fractions II. and III. is propyl alcohol. The first drop of free water came over in repeated experiments at 89·1°, and sharply indicates the beginning of the isobutyl alcohol. Fraction IV. was collected in two layers, showing that the mixture of constant boiling-point contains more water than the alcohol is capable of dissolving at room temperature. The rise of temperature, after the last drop of water contained in the sample had distilled over, was so sudden that the curve shows an almost perfect right-angle at this point. The remainder of the isobutyl alcohol came over in anhydrous condition in fraction V., after which amyl alcohol was collected in the remaining fractions.

The distillation of the same sample, carried out under identical conditions except that aluminium rings were used in the place of copper ones, gave somewhat curious results, which seem worth recording. They are plotted in the dotted curve (fig. 5). This curve is, for the first 40% of distillate, practically identical with the copper ring curve, except for a slightly sharper separation in fraction I., probably due to the difference in the specific heat, and therefore rate of warming up of the two metals. The appearance of the first drop of free water at the same point has already been noted. After 40% of the distillate had come over, the temperature being constant at 89·1°, it suddenly dropped. At the lowest point reached, 79·6°, the escape of gas carrying white fumes with acrid smell was noticed. The thermometer then rose again repeatedly, when at 97·2° a similar drop and subsequent rise occurred, which was once more repeated at 103·0°. The distillation was then stopped, as a solid deposit was noticed in the distilling flask. The residue in the flask set solid on cooling, and after steam-distilling the alcohol from flask and column, the solid was found to be voluminous aluminium hydroxide, of which more than 200 g., equivalent to 35 g. of Al_2O_3, was collected.

The aluminium rings were found to be attacked very considerably, those in the lower layer being pitted and pierced with holes, and a good deal of metal was dissolved away. This observation confirms the results of previous workers (Gladstone and Tribe, J. Chem. Soc., 1876, **29**, 158; Seligman and Williams, J., 1918, 160 T), who found that the higher alcohols when anhydrous attacked aluminium violently, and that such action is inhibited by traces of moisture.

As an explanation for the abnormal distillation curve it is suggested that at the time when the temperature drop occurred the alcohol in the flask and lower part of the still-head was anhydrous. In reacting with the aluminium, alcohol was used up by the formation of aluminium butoxide to such an extent that the amount of vapour reaching the thermometer was insufficient to keep it heated. The failure of vapours to pass through the still-head caused air to diffuse back, and as the condenser was at that time wetted with a mixture of butyl alcohol and water, traces of the latter on reaching the rings stopped the reaction. Hence, the sudden rise and second drop of temperature when the water was again cleared out from the still-head and when this phenomenon was repeated. The most interesting feature in this connexion from the point of view of fractionation is the fact that when the action occurred, and judging from the experiment with copper rings, the column must have still contained 69 c.c. of the mixture of butyl alcohol and water of constant boiling point, partly in the form of vapour and partly in the form of condensate. The division between the moist and anhydrous portions of the column was therefore an extremely sharp one, and the rings acted as a perfect seal against moisture. Whilst this experience shows a drawback of aluminium, which in many cases is preferred to other metals, it indicates possibilities of usefulness of ring-packed still-heads which have not yet been exploited.

In conclusion, I wish to express my indebtedness to Professor Sydney Young, F.R.S., for his helpful criticism, to Mr. H. E. Burgess for permission to publish the graph and data of the fusel oil distillation, to Messrs. Barnsley Main Colliery Co., Ltd., for their permission in regard to the crude benzol curve, and to Messrs. C. H. Butcher, A. H. Raine, and F. S. Shadbolt for carrying out the experimental work and preparing the drawings.

Discussion.

The Chairman asked Dr. Lessing if it would be possible by using the apparatus described to increase the strength of the ordinary 93½% industrial spirit. Those who in the course of their work used alcohol as a precipitant for dextrins, gums, etc., obtained large volumes of low strength alcohol (80%). It was tedious to use lime for dehydrating such spirit, and it would be a great convenience if the column was applicable in such a case.

Dr. M. W. Travers said that the probability that any particular ring would be so placed that the opening at the side would be exactly at the bottom, which was the only condition under which it would facilitate drainage, appeared to be very small. The same remark applied to the opening between the edge of the feather and the inner wall. Would it not be better to make the rings of perforated metal?

Dr. R. C. Farmer asked if any definite comparisons had been made with the original plain rings and the present ones, which were split. In his experience the split rings tended to link together, and this would presumably interfere with their efficiency.

Dr. F. M. Perkin said that channeling was very tiresome in most cases, and even in this case surely there was a chance of it taking place. In distillations in reference to benzol and toluol, he had used shell turnings, which was the only material available at the time, and to prevent channeling wooden rings were placed between the turnings, so that the vapour was diverted into the centre again. He found that extremely useful, and it was also useful in scrubbing. Working on the laboratory scale, he had prevented radiation by using a silica tube with pear-shaped condenser and an evacuated outer casing; this on a small scale worked very well, but on a commercial scale it would probably be too expensive.

Mr. Christensen asked if rings of non-conducting metal would be preferable to aluminium.

Capt. C. J. Goodwin said he was not satisfied that it was always necessary to have such a long tube as suggested by Dr. Lessing. He also thought it would be a good plan to decrease the size of the rings from the bottom upwards; that would lessen the surface and reduce the quantity that had to drain back, and the quantity of liquid that was retained on the filling. The size of the rings was really of very great importance, and experience showed that the greatest scrubbing surface was necessary at the top of the column.

Mr. P. Parrish said that Dr. Lessing had failed to deal with the practical aspect of the question, and there shauld have been some comparisons between the laboratory experiments and actual practical working. The author appreciated the importance of surface area and local pools as important factors affecting efficient fractionation, but he would find that columns of the character described when applied on the practical scale would be infinitely better if arranged in such a way as to afford actual and positive bubbling. The fractionation of alcohol was still effected on the large scale in Coffey stills, where bubbling was the salient principle.

Dr. H. P. Stevens asked for information as to the time taken to fractionate the liquid when comparing different distillation heads.

Dr. Lessing, in reply, said that so far the dimensioning of still-heads or scrubbers had been entirely empirical. The graduation of the rings, as suggested by Capt. Goodwin, had already been applied on the large scale. Dilute ethyl alcohol (80—93%) could easily be fractionated to a concentration of 95%; beyond that it became theoretically impossible. With regard to Dr. Travers' point, the majority of rings did get into a position where drainage was facilitated, even if some were lying with the gap on top. The liability of the rings to nest in each other was dependent on efficiency in manufacture, because, according to the thickness of the material, he thought it would be possible to make the slit of such a size that this would not happen. The trouble so far had been that they had not had sufficient control over the raw material; there was sometimes a spring in the material if it were not annealed to the correct hardness, and the rings then opened out more than they were intended to. He had tried the effect of dehydrating agents on alcohol fractions, but they were not of very great use. With any alcohol higher than propyl alcohol, with repeated distillations it was possible to get out practically 50% of the water each time, so that with two or three distillations it was possible to get 70 or 80% more of the alcohol in the anhydrous form without the aid of a dehydrating agent. With regard to the channeling, mentioned by Dr. Perkin, with shell turnings there would be the very difficulty which was avoided with rings, namely, a corkscrew action, which carried the condensate down and allowed the vapour to rise, whilst in the case of the rings it was broken and deflected. Vitreous rings could not be made on the small scale in the thin sections in which they would be required, and on the whole, he was inclined to the opinion that metal rings were preferable on account of their conductivity and quicker exchange of heat between the two phases. He did not agree with Mr. Parrish's remarks; a set of experiments had been carried out during the war on the debenzolisation of benzolised oil in which an ordinary distilling column of the bubbling type had been displaced by a plain gas pipe which had exactly half the cubic capacity of the other still, and was filled with rings; the debenzolisation efficiency rose from 60% to 92 or 93%, and inversely the purity of the mixture of benzol and toluol was increased to a similar degree, so that the benzol-extracting capacity of the return oil was about 90% as against 60—70% in the other case. He had found that channeling was very much more likely to happen with perforated rings than with solid rings; there was a straight run up the tube and dripping right down without the deflection which was obtained with the solid ring. The rate of distillation was very important and was recorded in every case. Generally a higher rate of distillation could be employed when contact rings were used without impairing the efficiency.

Meeting held at Textile Institute on March 4, 1921.

MR. JOHN ALLAN IN THE CHAIR.

NORMAL AMYLBENZENE AND SOME OF ITS DERIVATIVES.

BY L. GUY RADCLIFFE, M.SC.TECH., F.I.C., AND N. SIMPKIN, M.SC.TECH., A.I.C.

The present investigation refers only to normal amylbenzene and its derivatives, as considerable difficulty is experienced in preparing pure iso-amyl compounds, and the ordinary iso-compound is easily converted into a tertiary compound, whilst on the other hand straight-chain compounds can be readily obtained pure.

Normal amylbenzene, $C_6H_5.CH_2.CH_2.CH_2.CH_2.CH_3$, was discovered by Schramm (Annalen, 1883, 218, 388); its preparation by the action of sodium on a mixture of benzyl bromide and normal butyl bromide has been described in considerable detail. The hydrocarbon is a colourless liquid with an agreeable odour and boils at 200·5°—201·5° C. under 743 mm. pressure.

In the research to be detailed, Schramm's method of preparation was used with certain modifications, for example, benzyl chloride was used in place of the exceedingly unpleasant benzyl bromide, with good results. The adoption of this method was further influenced by the following considerations:—(1) Normal butyl alcohol can be readily obtained almost pure, whereas amyl compounds from which the required hydrocarbon could be made are extremely difficult to obtain pure. (2) The mechanism of the reaction is fairly simple. (3) It is possible that important derivatives of *n*-amylbenzene may be discovered and thus afford a means of utilising the considerable stocks of *n*-butyl alcohol which are available. In reality the reaction does not correspond exactly to the equation:—

$$C_6H_5.CH_2Br+2Na+Br.C_4H_9=C_6H_5.C_5H_{11}+2NaBr.$$

Subsidiary reactions occur in which, *e.g.*, two benzyl radicals unite to give the well-known dibenzyl and further, two butyl radicals couple to form *n*-octane; and it is clear that other reactions must take place, as there is always formed a large quantity of thick oil having a very high boiling point. The effect of these secondary reactions is to reduce the yield of *n*-amylbenzene to about 25% of the theoretical yield.

Experimental.

The first preparations of *n*-amylbenzene were made by treating a mixture of benzyl bromide and normal butyl bromide with sodium, the conditions being modified in various ways with a view to increase the yield of amylbenzene and decrease the amount of by-products; with this same object in view benzyl chloride was substituted for the benzyl bromide. The effect produced by diluting the reacting mixture with benzene was also exhaustively studied.

The investigation of the *n*-amylbenzene itself was, after determining its physical properties, mainly confined to a partial study of its sulphonation, in which was included the preparation and properties of a monosulphonic acid and its barium salt, also the corresponding sulphonic chloride and sulphonamide and a phenol. The constitution of the sulphonic acid has been determined, whilst the mononitro compound has been prepared and its properties investigated.

In order to establish the constitution of *n*-amylbenzene with certainty, *n*-amyl bromide was synthesised from *n*-butyl alcohol and coupled with bromobenzene in order to produce amylbenzene by a very different method. A comparison of this amylbenzene with that made by Schramm's method showed that they were identical. The *n*-butyl bromide used in the experiments was made by treating a mixture of commercial butyl alcohol (sp. gr. 0·8133 at 15·5° C., b.p. 115°—118° C.) and red phosphorus with bromine. Using 212 g. of the alcohol, 36 g. of phosphorus, and 255 g. of bromine, a yield of 87·7% was obtained. Many experiments were carried out in order to ascertain the conditions under which the best yield could be obtained.

The benzyl bromide was made by the direct bromination of boiling toluene, and the yield of pure product was about 60%, obtained in the form of a colourless liquid, b.p. 198°—202° C. This product kept well and did not appear to undergo decomposition even after standing for several months.

The benzyl chloride used in the experiments was obtained by the fractionation of the commercial product, the portion boiling from 176° to 179° C. being used for the experiments. It appears worth recording that much uncertainty exists as to the true boiling point of benzyl chloride.

The *n*-amylbenzene was prepared as follows, using 128 g. of benzyl bromide, 103 g. of *n*-butyl bromide, and 34·5 g. of metallic sodium. Sodium in the form of wire was added gradually to the mixed benzyl and butyl bromides; the temperature of the mixture soon rose to 35° C., whereupon it was cooled by immersing the vessel in water. After about one-fourth of the sodium had been added, the temperature being kept below 50° C., the action appeared to slacken and the mixture was heated to about 80° C. Fresh quantities of the sodium wire were added, and when about half the sodium had been added the mixture was allowed to stand overnight. The contents of the vessel now consisted of a solid layer (sodium bromide) surmounted by a pale yellow liquid. As the large amount of sodium bromide present apparently hindered the reaction, the mixture was diluted by the addition of 100 c.c. of dry benzene and gently boiled on the water-bath. The remainder of the sodium was gradually added, and the boiling continued for a further 25 hours to complete the reaction. At this stage the liquid was dark yellow in colour and possessed a pleasant odour, while the whole of the sodium had been converted into the bromide. The mixture was heated by means of an oil-bath, and about 60 c.c. distilled off. The residue was then steam-distilled to obtain the amylbenzene, which collected on the surface of the water as a bright, colourless liquid. Soon crystals began to appear in the distillate, whereupon the receiver was changed and steam distillation continued for another hour, making in all a total of 9 hours. The residue in the distillation flask consisted of the sodium bromide solution, upon the surface of which floated a thick, dark yellow oil. The white, needle-like crystals melted at 52° C. and were dibenzyl. The thick oil has not yet been investigated.

The colourless oil resulting from the steam distillation was carefully fractionated, and gave a 27·6% yield of crude *n*-amylbenzene, b.p. 195°—205° C. Further quantities of dibenzyl were also obtained. The yield is not good, and the secondary reactions resulting in the formation of dibenzyl, octane, and the high-boiling thick oil, are not at present clear.

It was found not to be advisable to dilute the reacting mixture with benzene at the beginning of the experiment. In the other preparations of amylbenzene, benzyl chloride was used with butyl bromide both with and without dilution with benzene, and it was found that the benzyl chloride gave just as good a yield as the benzyl bromide. As a result of many experiments, in which the conditions were slightly varied, it was concluded that the following conditions tend to give the best yield of amylbenzene:—

1. The sodium wire (sodium cut into slices was also used, but was slower in its action, especially towards the end of the reaction, unless the shavings were very thin) should be added slowly to the mixture of benzyl chloride and butyl bromide, the latter being in slight excess of the theoretical amount required, and the mixture shaken or frequently stirred.

2. The reacting mixture should not be diluted with benzene, and should be kept as cool as possible, *i.e.*, compatible with the continuance of the reaction.

3. To complete the reaction, it is advisable to let the whole mixture stand for a few days with an occasional shaking, since the application of heat, or the development of heat during the reaction, lowers the yield of amylbenzene and increases the amount of the higher boiling hydrocarbons. A diluent with a boiling point lower than that of benzene, such as pure dry ether (free from any alcohol), might give better results, as the mixture would boil at a considerably lower temperature.

Purification of crude amylbenzene.

The fraction boiling at 195°—205° invariably contained traces of the benzyl halide, and to remove this, the crude hydrocarbon was mixed with alcoholic potash and gently boiled in an oil-bath for 9 hours, after which the excess of alcohol was distilled off and the residue distilled with superheated steam. The upper layer of distillate was heated to 105° in contact with thin shavings of metallic sodium for 7 hours. The product was free from halogen. The still impure amylbenzene was then fractionated, using a 4-bulb column, and the product boiling between 200·5° and 202° C., under 761·2 mm. pressure, collected as pure amylbenzene. From careful observation the boiling point would appear to lie between 201° and 202° C. at 761·2 mm., agreeing with the figures given by Schramm, viz., 200·5°—201·5° C. under 743 mm.

Properties of n-amylbenzene.

Normal amylbenzene is a colourless liquid possessing a rather pleasant odour. It is readily soluble in alcohol, benzene, ether, carbon bisulphide, methylal, chloroform, carbon tetrachloride, and glacial acetic acid. If sulphuric acid is added to the hydrocarbon, drop by drop, a slight brownish sediment forms upon the addition of each drop, and with an excess of acid, or on warming, the amylbenzene dissolves (*cf. infra*). The hydrocarbon does not dissolve in cold 70% nitric acid, but does so on warming the mixture; on cooling, however, the amylbenzene comes out of solution. Further details of the nitration are given later.

The density was found to be:—at 15·5°/15·5° = 0·8664; at 15·5°/4° = 0·8651; at 22°/22° = 0·8624, and at 22°/4° = 0·8602. Schramm gave the density of his amylbenzene as 0·8602 at 22° C., but does not state whether this is compared with water at the same or some other temperature (*loc. cit.*). A quantity of amylbenzene was distilled, and the refractive index of each 5 c.c. of distillate determined by means of the Pulfrich instrument; the index in each case was $n_D^{15} = 1·4751$.

Sulphonation of n-amylbenzene.

After a number of preliminary experiments had been performed, 10 g. of the hydrocarbon was sulphonated by the gradual addition of an equal volume of concentrated sulphuric acid, with frequent shaking. A brownish-white substance was produced with the addition of each drop of acid,

and a slight development of heat occurred. After all the acid had been added the resulting mixture was a brownish-white liquid containing globules in suspension, presumably of unchanged amylbenzene, as the characteristic odour still persisted. To complete the reaction the contents of the flask were heated on the water-bath with frequent shaking for 2 hours, and finally for ½ hour over a small flame. The liquid, now dark brown in colour, was poured into about 250 c.c. of distilled water and neutralised with barium carbonate, followed by boiling for ½ hour and filtering. The filtrate rapidly deposited fine white, shining, needle-like crystals which appeared flaky when dry, and were very soft in texture; the residue, consisting of barium sulphate and carbonate, was repeatedly extracted with boiling water, and from each extract small crops of crystals were obtained upon evaporation. Each crop was analysed to determine whether mixtures of the mono- and disulphonic acids were formed under the above conditions. The theoretical percentage of barium in barium amylbenzenemonosulphonate, $(C_{11}H_{15}SO_3)_2Ba$, is 23·21%; by analysis, 23·26% was found. Further experiments led to a 54% yield of the monosulphonic acid being obtained; the barium salt crystallised without water of crystallisation.

Preparation of the sulphonic chloride and sulphonamide of n-amylbenzene.

To determine whether the barium amylbenzenemonosulphonate was a single isomer or a mixture of two isomers, a portion of each crop of crystals of the barium salt was converted into the sulphonic chloride and thence to the corresponding sulphonamide.

The sulphonic chloride was prepared by heating a mixture of the finely-powdered barium amylbenzenesulphonate with powdered phosphorus pentachloride on a water-bath for two hours, with occasional shaking, adding the mixture to water, and extracting the oil with ether. On evaporation the ethereal solution yielded a pale brown oil which solidified to flat, needle-shaped crystals of the sulphonic chloride; this melts at 38°—39° C., it has a peculiar unpleasant odour, and has the property of remaining liquid at the ordinary temperature for a considerable time. It is readily soluble in ether, petroleum spirit, chloroform, benzene, carbon tetrachloride, and carbon bisulphide, but is only sparingly soluble in cold alcohol.

The sulphonamide was prepared from each batch of sulphonic chloride by heating with powdered ammonium carbonate for about 2 hours, grinding the product with several quantities of cold water, and crystallising the pale brown substance thus obtained from dilute alcohol, from which the sulphonamide separated in white, hair-like, glistening crystals somewhat resembling glass wool. Every batch of crystals melted at the same temperature viz., 86°—87° C. It would thus appear that only one isomer was present in the barium salt, as obtained by the above method.

The sulphonamide was analysed by a modification of the Kjeldahl method, and was found to contain 6·18% of nitrogen. Calculated for $C_6H_4.(C_5H_{11}).SO_2.NH_2$, N = 6·17%.

In order to determine the orientation of the sulphonic acid and its derivatives, the amylbenzenesulphonamide was oxidised by boiling with an alkaline solution of potassium permanganate (Pinner, Ber., 1888, 21, 243), and the sulphaminebenzoic acid isolated in the usual way and recrystallised from boiling water; it was obtained in small, flat, needle-shaped crystals, almost colourless, and melting at 278°—280° C. with decomposition. This observed melting point agrees with that of *p*-sulphamine-benzoic acid, whence it may be concluded that the acid formed by the sulphonation of *n*-amylbenzene as described above is *n*-amylbenzene-*p*-sulphonic acid, and further, that no appreciable quantity of any other isomer is formed.

The free sulphonic acid itself was obtained from the barium salt in the form of very hygroscopic, needle-shaped crystals, which were exceedingly soluble in water, and further, the potassium, silver, and calcium salts have been prepared.

n-Amylphenol.

About 5 g. of potassium amylbenzene-*p*-sulphonate was mixed with 14 g. of powdered caustic potash and transferred to an iron tube, sealed at one end. The powder was washed down with 2 c.c. of water and the mixture stirred. The temperature was gradually raised to 330°—340° C. and kept thereat for 1 hour, whilst a slow stream of hydrogen was passed into the top of the tube throughout the experiment to prevent oxidation of the phenol. After cooling, the dirty, greenish mass obtained was dissolved in about 40 c.c. of water and the solution acidified, whereupon a thick, pale brown oil separated on the surface. This oil was extracted with ether and distilled, yielding a colourless fraction, boiling at 262° C. and giving reactions corresponding to a phenol; it is very sparingly soluble in boiling water, readily soluble in caustic soda, ether, acetic acid, or alcohol; the alcoholic solution gave an olive-green coloration on the addition of ferric chloride, which was discharged by hydrochloric acid. When chilled in a freezing mixture, the amylphenol formed white crystals which melted at the ordinary temperature. It is not considered that this compound was obtained in a chemically pure condition. The benzoylamylphenol, made in the usual manner, crystallised from alcohol in white needles, m.p. 52° C. A bromo-derivative was also prepared by adding bromine to the amylphenol dissolved in glacial acetic acid and pouring into water; the product, after repeated crystallisations from dilute alcohol, was obtained in colourless crystals, m.p. 88°—89° C.

Nitration of the amylbenzene.

Attempts to nitrate amylbenzene with a mixed acid composed of sulphuric acid (sp. gr. 1·84) and nitric acid (sp. gr. 1·42) did not give very satisfactory results, as it appeared that nitration was not, in any experiment, complete. Mononitroamylbenzene was, however, obtained by the following method:—40 g. of fuming nitric acid (sp. gr. 1·508) mixed with 20 g. of glacial acetic acid was added slowly to 20 g. of amylbenzene dissolved in a further 20 g. of glacial acetic acid, the temperature being kept below 20° C. by external cooling; the mixture gradually turned brown in colour, and, after the addition of all the nitric acid, which occupied about 1 hour, was allowed to stand, when it separated into two layers. When the whole was heated for ½ hr. in a bath of water at 50° C., brown fumes were evolved and a homogeneous liquid was produced. After standing for 12 hours, the heating was resumed for a further hour, the mixture cooled and poured into water containing lumps of ice, whereupon a yellow, oily liquid was thrown down. The mixture was made alkaline with caustic soda solution and extracted with ether. The ether solution, after drying over anhydrous sodium sulphate, was distilled, leaving a yellow liquid having a characteristic odour, the bulk of which distilled under 14 mm. pressure at 158°—159° C. A determination of nitrogen gave a slightly high result, indicating possible contamination with a small amount of the dinitro-compound. Thus prepared, mononitro-*n*-amylbenzene is a pale yellow oil of sp. gr. 1·0650 at 15° C. and miscible with the usual organic solvents. When oxidised by the process used for the sulphonamide, *p*-nitrobenzoic acid, m.p. 236°—237° C., was

obtained; it was concluded that the nitro-compound was *p*-nitroamylbenzene.

At this stage the preparation of *n*-amylbenzene by a quite different method was undertaken in order to be certain that the compound hitherto studied was in reality *n*-amylbenzene. The process chosen was to treat a mixture of monobromobenzene and synthetically prepared *n*-amyl bromide with metallic sodium, when the following reaction would take place:—$C_6H_5Br+2Na+BrC_5H_{11}=2NaBr+C_6H_5.C_5H_{11}$. For this reaction *n*-amyl alcohol was synthesised from *n*-butyl alcohol according to the method of Adams and Marvel (J. Amer. Chem. Soc., 1920, 42, 311—315). This, briefly described, entails the conversion of *n*-butyl alcohol to the nitrile *viâ* the intermediate stage of the butyl bromide, then the hydrolysis and esterification of the nitrile by means of 95% ethyl alcohol and strong sulphuric acid to give ethyl valerate, and finally the reduction of the latter by means of sodium and absolute ethyl alcohol to *n*-amyl alcohol. This synthetically prepared *n*-amyl alcohol was then converted into its bromide by means of the phosphorus halide method, and the resulting *n*-amyl bromide coupled with bromobenzene, using metallic sodium as usual. It is necessary to use absolute alcohol when reducing the ester with sodium, as otherwise the reaction fails. All the materials were highly purified at every stage. The final coupling of bromobenzene and *n*-amyl bromide with metallic sodium gave a product which was identical with that originally prepared by the interaction of benzyl chloride and butyl bromide. The outstanding feature of this last method of preparation is the fact that the yield of *n*-amylbenzene is between two and three times as great as in the previous experiments; it would thus appear easier to introduce an aliphatic side chain into a benzene ring than to add another group to an already existing side chain.

In concluding this paper, it may be mentioned that a highly-odourous aldehyde has also been obtained, but the work has been interrupted, and a description of this product cannot be given at present.

Discussion.

Captain F. S. Sinnatt said that *n*-amylbenzene would probably be converted into an α-methyl derivative of tetrahydronaphthalene with considerable ease; such a compound would have a very high boiling point and a considerable percentage might be present in the residual oil obtained by the authors, which might yield on examination some interesting compounds.

Mr. H. G. Shatwell said if the ring were chlorinated and the end of the chain were also chlorinated, and the resulting compound treated with sodium, it might be possible to cause that ring to close as suggested. Had any attempt been made to reduce the nitro-compound described?

Mr. N. Simpkin, in reply, said that a large amount of work had already been done in America on the utilisation of butyl alcohol. Apparently the oil might contain such a substance as benzylamylbenzene. In reply to Mr. Shatwell, certain chlorine derivatives of this hydrocarbon had been prepared, but it had been found that instead of the end of the chain being chlorinated, a mixture of compounds resulted. Furthermore, in order to produce a naphthalene ring as Mr. Shatwell suggested, the side chain would require to be chlorinated at the δ-carbon atom, not the ε- or end carbon atom, in order to couple up with the benzene ring. The compound had been brominated, and several distinct compounds with 1, 2, and 3 atoms of bromine obtained, but not in the pure state. The nitro-compound had not been reduced owing to lack of time.

PROF. P. PHILLIPS BEDSON IN THE CHAIR.

THE EFFECT OF SOME PHYSICAL CONDITIONS ON CALCIUM SULPHATE CEMENTS.

BY C. L. HADDON.

Anhydrous calcium sulphate cement bears a number of different names, such as flooring plaster, "Estrich gips," and dead-burnt plaster. A slightly modified form is called Keene's cement.

The actual setting time of flooring plaster depends on the temperature and duration of heating used in its manufacture, but subsequent conditions have the same comparative effect on different samples of plaster.

It was long ago shown that the setting of flooring plaster is due to the anhydrous salt dissolving and being precipitated as crystals of the less soluble dihydrate. These crystals in dilute solutions form radiating bundles of needles, and it was assumed that this occurred in its use as a cement, and that fracture of the cement was caused by the breaking of the interlocking crystals. It was also shown by using a dilatometer that in setting there was first a contraction followed by an expansion. This was explained by Davies as being due to the formation of orthorhombic crystals spontaneously changing to monoclinic crystals. Data as to its superficial expansion—the more important from the practical point of view—are lacking. According to Lunge's "Technical Methods of Chemical Analysis," "increase in volume is not a property of dead-burnt plaster." On the other hand, other authorities state that it expands on setting, but no figures are given. The apparatus used for measuring expansion was Le Chatelier's, as laid down in the Engineering Standards' specification for Portland cement. The dimensions of this instrument are so designed that for relatively small expansions (less than 1%) the measured expansion in centimetres is approximately equal to the percentage linear expansion. It is not a suitable instrument for measuring expansion during the plasticity stage of setting.

The same flooring plaster was used throughout these experiments. Three parts by weight of plaster was mixed with one part of water or solution and placed in the cylinder, and the expansion was measured at different times. The subjoined table shows that:—

(1) The expansion was least when accelerating solutions were used, and greatest when retarders were used.

(2) Wet set plaster, using a 5% solution of a sulphate as accelerator, although reaching its maximum strength within 24 hours, yet continued to expand during recrystallisation.

(3) Wetness has a great effect on tensile strength. With plaster kept weakened in this way, a very much greater expansion resulted. The degree of wetness affects expansion.

(4) The expansion under normal conditions is very small—about 0·1%—and ceases within seven days, *i.e.*, the time for complete setting or drying.

In the case of calcium chloride the expansion was measured after the first day; a further expansion of 0·7% took place when thoroughly re-wetted due to drying before complete hydration.

No attempt was made to measure expansion while the cement was still plastic.

The cause of the expansion is obvious—it is due to the pushing apart of the mass by crystals as they

are formed. An expansion of 5% can easily be produced by using a retarder, and keeping the cement wet.

In dry room.	% Expansion from time of loss of plasticity.			
	1 day.	4 days.	7 days.	14 days.
Mixed with water..	0·08	0·12	0·17	—
„ 5% soln. $CaCl_2$	—	0·40	0·75	0·97
„ 5% soln. K_2SO_4	0·06	0·07	0·08	No further
„ 5% soln. $FeSO_4$	0·06	0·07	0·08	increase.
Mixed with water placed in water after 1½ hrs.	1·0	1·5	1·85	—

The amount of expansion has an effect on the tensile strength. Briquettes which have expanded 5% have less than a quarter of the strength of similarly made briquettes allowed to dry in air, when the expansion is very much less. Similarly, in test-pieces where the plaster was placed in water six hours after making the briquette, and the briquette broken after seven days when still wet, the tensile strength averaged 200 lb. per sq. in., while when the briquette was allowed to dry in air and placed in water only for the seventh day, the average tensile strength was 250 lb. per sq. in.

In a recent paper (J., 1920, 165—168 T) the author mentioned the weakening of flooring plaster by wetness, and it was suggested that it was due to the lubricating action of water. In order to investigate this, test-pieces were placed in water after six hours, taken out after 14 days, and then left in a warm, dry room till they ceased to lose weight. Briquettes were immersed in different liquids for 24 hours and then broken.

The average tensile strength of the dry briquettes was 470 lb. per sq. in.; after immersion in paraffin it was 470 lb.; in thin lubricating oil, 470 lb.; in methylated spirit, 470 lb.; in a mixture of 2 pts. of spirit to 1 of water, 320 lb.; in a mixture of 1 part of spirit to 2 of water, 250 lb.; in water, 200 lb.; and in concentrated calcium sulphate solution, 200 lb. The test with thin lubricating oil gave the same result at the end of 10 days; figures identical with those of the 24-hr. tests were also obtained with water (10 mins.) and concentrated calcium sulphate solution (1 hour).

Thus mineral oils have no effect on strength, while with mixtures of alcohol and water the loss in strength is dependent on their proportions. Water reduces the tensile strength by one half, as does a concentrated solution of calcium sulphate. Leaving in water for ten minutes, provided that the whole cross-section of the cement is wetted by capillary action, has the same effect, showing that it is not due to solubility of the set cement in water. The small amount of water necessary is shown by the fact that if one end of the test-piece is placed in water, the same weakening effect is produced by the water creeping up through capillarity. In the same way crushing strengths are reduced from about 2 tons per square inch to half that amount.

There is no accepted explanation of lubrication. It seems curious that oil should not act as a lubricant, while water does. Oil certainly acts as a lubricant when one slab of set flooring plaster is rubbed over another. In metals, the crystals are supposed to be covered with some amorphous intercrystalline cement which is stronger than the crystals, which break in cases of fracture. It is possible that some such amorphous calcium sulphate dihydrate exists, and this is affected by free water. Our present knowledge of physical phenomena is not sufficient to justify a full explanation.

The cementing power of calcium sulphate cement may be described as follows:—Crystals of the dihydrate grow in the form of needles, until there is great frictional resistance to disruption and also interlocking. Breaking is due largely to this frictional resistance being overcome, and not to the breaking of the crystals themselves, as is the case with metals.

The value of all published data on the mechanical strength of flooring plaster is impaired by the fact that no standard has been laid down as to the condition of the briquette on breaking. The popular method seems to be to keep the briquettes in a more or less damp room during setting. The effect of different amounts of free water would considerably vitiate the results. The fairest way is to do precisely as is done with Portland cement—leave the briquettes in the moulds for 24 hours, take them out and place them in water, and then break the wet briquettes after a week; this would give comparable results as regards the effect of expansion, and eliminate error as regards wetness. The proportion of flooring plaster to water by weight should be 3 to 1, as this gives a plastic mass of uniform composition, while deviations from these proportions give cements of different strengths.

Communications.

A MODIFICATION IN THE COMPOSITION OF IODINE SOLUTION FOR THE REICH TEST.

BY H. M. LOWE, M.SC.

Standard iodine solution used for testing gases for sulphur dioxide may be conveniently made by substituting for the potassium iodide in which the iodine is dissolved a proportion of caustic soda, insufficient to react with the whole of the iodine, but sufficient to form enough sodium iodide to dissolve the remaining iodine. The formula recommended is: Iodine, 127 g.; caustic soda, 30 g.; water, to 10 litres. Thus the 30 g. of caustic soda replaces 150—180 g. of potassium iodide. The iodine reacts with this to give a solution of iodide and iodate and is quantitatively released as free iodine on acidification with a large or small excess of acid. The sulphur dioxide in the gas it is desired to analyse acts in this way in $N/10$ solution without further addition of free acid. When the solution is used in great dilution, *e.g.*, $N/100$ to $N/1000$, as in treating exit gases, it is necessary to add some acid previous to use.

Experiments with this solution showed that the theoretical amount of iodine is always liberated on acidification, whether with a large or small excess of acid. Titration with standard thiosulphate of the iodine thus liberated forms a convenient method of standardising the solution for use. It is immaterial whether the acid is added all at once to the iodine or in small portions as the titration proceeds, but the latter method avoids the iodine being thrown out of solution at any time.

If desired the solution may be titrated with free SO_2 without addition of acid.

Comparison tests on the inlet gases to a Grillo oleum plant showed identical results with the ordinary solution or with the modified solution.

When the solution is diluted to 10 times its bulk it forms a reagent for testing the exit gases from the converter. In this case it is necessary to add to the solution to be tested a small amount of sulphuric or hydrochloric acid together with the starch indicator, as at the dilution used (about $N/1000$) a very appreciable concentration of acid is required before the iodide and iodate react instantaneously. At a dilution of $N/2000$ and a bulk of 200 c.c., on the addition of 6 c.c. of $N/10$ H_2SO_4 to a neutral mixture of iodide and iodate, a blue colour develops

slowly; with 7 c.c., however, the colour is obtained instantaneously. In the test, therefore, the addition of 1 c.c. of 10% H_2SO_4 is ample to ensure the instantaneous working of the indicator.

The sulphur trioxide present, together with the dioxide at the exit of the converter, would be thought to provide the necessary acidity, and, indeed, usually does so; but on one or two occasions the test failed, and the blue colour was discharged prematurely; it was found, however, that the addition of a little acid caused the blue colour to be re-formed. It is therefore advisable always to add a little acid to the test solution before commencing.

The $N/100$ solution may be standardised against thiosulphate in the same way as the $N/10$ solution and titrated with sulphur dioxide solution after acidification. Tested on exit gas from a Grillo converter the $N/100$ solution gave results identical with those using the ordinary potassium iodide solution.

The $N/10$ solution is sufficiently stable for ordinary purposes. Thus, a 10-litre bottle kept full showed no change in strength after a month, and one half full showed no change in strength after eight days.

H.M. Factory, Gretna.

THE ESTIMATION OF RESIN ACIDS IN FATTY MIXTURES.

BY DAVID McNICOLL, M.A., B.SC.

Twitchell's method for the estimation of resin acids in fatty mixtures (J., 1891, 1804), though it was a distinct advance on the methods then known, has many faults, as pointed out by Lewkowitsch (J., 1893, 502). Since that time no improvement has been made as regards accuracy accompanied by simplicity. The method detailed in this paper not only eliminates the faults of Twitchell's method but simplifies it by the substitution of methyl for ethyl alcohol and of naphthalene-β-sulphonic acid for gaseous hydrogen chloride.

It is well known that with Twitchell's method, resin acids undergo decomposition with the production of water-soluble acids of lower molecular weight, and it is the formation of these in varying amount which causes the irregular results. Lewkowitsch has also shown that esterification of the fatty acids is far from being complete.

Volumetric method.—About 2 g. of the mixture is dissolved in 20 c.c. of a 4% solution of naphthalene-β-sulphonic acid in dry methyl alcohol and heated under a reflux condenser for 30 mins. with the addition of several pieces of porous plate to ensure regular ebullition. A blank experiment with 20 c.c. of the sulphonic acid solution is also carried out for the same time, as the titration value increases slightly during the process. The best results are obtained by heating the flasks on an electric plate or asbestos wire gauze or in an oil-bath; esterification is not so complete when a water-bath is used. The contents of both flasks are then cooled and titrated with $N/2$ methyl alcoholic potassium hydroxide solution. For unknown mixtures the resin acids are calculated on the combining weight of 346, as suggested by Lewkowitsch.

Gravimetric method.—The neutralised solution obtained above is employed. The contents of the flask are transferred to a separating funnel—the volume being noted—and the flask washed out with an equal volume of water made slightly alkaline with potassium hydroxide. After shaking, the mixture is extracted with an equal volume of a mixture of ether and petroleum spirit, the flask having again been washed with the solvent. Separation is instantaneous. The small amount of insoluble soap that usually separates is drawn off with the soap solution, which is extracted twice in similar fashion. The united extracts are washed with a little 50% aqueous alcohol and the washings added to the resin soap solution, which is then acidified and extracted twice with ether.

Esterification of fatty acids.—Pure fatty acids are completely esterified by the method described, as shown by the following figures:—

	c.c. N/2 KOH used.	
	Experimental.	Blank.
Cotton oil fatty acids, 2 g. ..	8·50	8·50
Oleine, 2 g...	8·52	8·50
Palm kernel acid oil, 2 g.	8·57	8·50

The distilled olein, ruby red in colour, showed by titration after treatment the presence of 0·14% of free fatty acids calculated as oleic acid. With the palm kernel "acid oil" an acidity of 0·51% as oleic acid was found. The residual acidity in these two cases is doubtless due to colouring matter which, while being of an acid nature, is not esterified.*

Lewkowitsch has shown (*loc. cit.*) that Twitchell's method leaves 2—6% of fatty acids uncombined.

Treatment of resin.—On submitting resin to the process, partial esterification takes place amounting to 1—3% of the resin acids present; the amount varies for different qualities of resin.

A number of mixtures of known composition were examined by the methods described; the errors in the volumetric method varied between −0·22 and −0·56% and in the gravimetric method between −0·38 and +0·35%. The results obtained by Twitchell's method (as quoted by Lewkowitsch) show errors varying between −9·73 and +5·26%.

The following results were obtained from three different samples. In each experimental figure the value of the blank test has been deducted:—

Resin, g.	Before treatment. c.c. $N/2$ KOH.	After treatment. c.c. $N/2$ KOH.	Resin found. %
1·0473	6·00	5·93	98·8
2·4295	14·32	14·02	97·9
1·2159	7·08	6·90	97·4

That esterification had occurred was confirmed by saponification, 1·2 c.c. of $N/2$ potash being absorbed in the first experiment. The difference from the esterification value can be accounted for by oxidation of the alcohol.

That there is no appreciable production of water-soluble-decomposition products was proved in the first experiment by the recovery of 1·0375 g. of resin, which absorbed 5·88 c.c. of $N/2$ potash after evaporating the resin soap solution, dissolving in water, and extraction with ether after acidification.

Examination of mixtures of known composition.

Details of the examination of three mixtures by volumetric and gravimetric analysis are recorded below; in the experimental figures the value for the blank has been deducted.

Mixture.		Volumetric method.				Gravimetric. Resin. % Found.*
		Titration. c.c. $N/2$ KOH.		Resin. %		
Fatty acid.	Resin.	Calc.	Found.	Calc.	Found.	
2·0391	0·2652	1·53	1·57	11·51	11·84	11·73
1·4320	0·6091	3·46	3·52	29·84	30·28	30·23
1·0624	1·0080	5·73	5·70	48·69	48·45	48·88

* The amounts of resin found are corrected for the 5% unsaponifiable matter present.

Research Laboratory,
British Oil and Cake Mills, Ltd., Hull.

* Further experiment has substantiated this assumption. The estimation of true fatty matter in the by-products from the refining of cotton oil will be dealt with in a later paper.

A DIRECT METHOD FOR THE DETERMINATION OF DICYANODIAMIDE.

BY ERLING B. JOHNSON.

R. N. Harger (J. Ind. Eng. Chem., 1920, 12, 1107; J., 1921, 92 A) has recently described a gravimetric process for the determination of dicyanodiamide (cyanoguanidine) in cyanamide and mixed fertilisers, based on the precipitation of a compound of silver picrate and 1 mol. of dicyanodiamide, $C_6H_2(NO_2)_3OAg,C_2H_4N_4$.

Some years ago the present author, working with Mr. Berbom, isolated the same complexes as those described by Harger in the attempt to obtain a method for the determination of dicyanodiamide, but as it was important to have as rapid a method as possible, a volumetric process was worked out.

It is practically impossible to determine dicyanodiamide volumetrically by means of the above compound on account of the large excess of silver solution which must be used. On the other hand, it was found that under certain conditions the compound of silver picrate with 2 mols. of dicyanodiamide was so insoluble and changed so slowly into the mono-compound, thus:—

$$C_6H_2(NO_2)_3OAg,2C_2N_4H_4+C_6H_2(NO_2)_3OAg=2C_6H_2(NO_2)_3OAg,C_2N_4H_4$$

that a volumetric method could be based on the determination of the amount of standard silver solution used to effect the precipitation. It is necessary to use weak solutions, a low temperature, and excess of picric acid.

The method is carried out as follows: When the sample being analysed contains 5—15% of dicyanodiamide nitrogen 5 g. is used, or a correspondingly larger amount if less nitrogen is present. The sample is transferred to a 500 c.c. flask and 450 c.c. of cold water added. If the sample is calcium cyanamide or other product containing lime, glacial acetic acid is added to bring all the lime into solution as acetate. By this means the nitrogenous compounds present are dissolved much more rapidly and completely than without any acid. A small excess of acetic acid does not matter. Stronger mineral acids isomerise the nitrogen compounds. The solution obtained with acetic acid is suitable for a Kjeldahl determination of the total water-soluble nitrogen, but this is not possible if nitric acid has been used, as has been suggested, to shorten the period of shaking.

The flask is shaken in a machine for 3 hours, the solution is made up to 500 c.c. and filtered; 5 c.c. of 20% nitric acid is added to 100 c.c. of the filtrate, followed by 20 c.c. of sodium picrate solution heated to 40° C. (7·5 g. of picric acid neutralised with caustic soda and diluted to 100 c.c.), and the solution is cooled to about 5° C., and titrated with N/22·4 silver nitrate solution, which is added drop by drop with constant shaking. About 2 c.c. more silver solution is used than is required by the amount of dicyanodiamide believed to be present. The dicyanodiamide compound is precipitated in a more or less gelatinous form according to the amount of dicyanodiamide present. After vigorous shaking the mixture is stood aside for fifteen minutes at 5° C., during which time it is agitated two or three times, then diluted to 200 c.c. with cold water, shaken and filtered. The excess of silver solution used is estimated by titration with N/22·4 sodium thiocyanate in 100 c.c. of the filtrate after adding a further 5 c.c. of 20% nitric acid and about 2 c.c. of 5% ferric sulphate solution as indicator.

If 5 g. of the sample has been treated according to the method described, every c.c. of silver solution used corresponds to 1% of nitrogen as dicyanodiamide.

To obtain good results some corrections must be applied, but each observer should work these out for himself, as they will depend largely on the personal equation.

The corrections as worked out by the author are shown in the following tables.

Influence of the excess of silver solution.—As the compound of silver picrate with 2 mols. of dicyanodiamide changes into the compound with 1 mol. in presence of excess of silver salt, it is possible that such excess may influence the results. This is shown in the following table. Pure dicyanodiamide was used with the addition of 1 c.c. of 20% nitric acid.

Dicyano-diamide-N.	Excess of silver solution.				
	2 c.c.	3 c.c.	4 c.c.	5 c.c.	6 c.c.
0·05 g.=5%	98	103·6	103	105·3	108
0·10 g.=10%	99·5	99·7	100	100·9	101·5
0·15 g.=15%	97	97	97·5	98	98·7

Note.—In this and the succeeding tables the figures given are the percentages of the amount actually present.

Influence of increasing addition of nitric acid.

Dicyanodiamide-N.	Excess of 20% nitric acid.		
	1 c.c.	5 c.c.	10 c.c.
0·05 g.=5%	98	94·8	90
0·10 g.=10%	99·5	97·4	95
0·15 g.=15%	97	96·4	95·5

Influence of nitric acid and different amounts of calcium acetate (the latter would be present in analysing samples of calcium cyanamide or other products containing lime).

Dicyano-diamide nitrogen.	Additions.						
	Nitric acid.	1 c.c.	1 c.c.	1 c.c.	5 c.c.	5 c.c.	10 c.c.
	Calcium acetate.		1 g.	5 g.	1 g.	5 g.	5 g.
0·05 g.=5%	—	98	90	80	102	82·4	84
0·10 g.=10%	—	99·5	98	89	99·8	92·4	95
0·15 g.=15%	—	97	98·7	94·7	97·5	95·3	96

Influence of temperature on the precipitation.—2 c.c. excess of silver solution was used in each case.

Dicy. N present.	5° C.	10° C.	15° C.	20° C.	25° C.
0·10 g.=10%	99·6	98	96·4	90·5	85·1
0·05 g.=5%	98	95·5	92	85·5	70

It will be obvious that when working with calcium cyanamide the use of 5 c.c. of 20% nitric acid per 1 g. of calcium acetate present and the addition of 2 c.c. excess of silver solution will give good results without any corrections.

A characteristic feature of the precipitation of dicyanodiamide with a greater excess of silver solution and picric acid is the change of the gelatinous di-compound first precipitated into the small crystals of mono-compound; this occurs more or less rapidly according to the excess of silver and the concentration.

The method has been tested in the presence of urea and dicyanodiamidine (guanylurea), but neither of these compounds was found to influence the results.

The following table shows the reliability of the method and gives the results of the analyses of very old samples of calcium cyanamide.

When chlorides and soluble sulphides are present a blank test must be carried out by titrating the silver solution without addition of picric acid.

Sample.	New method (picrate).				Old method (modified Caro).			
	Cyanamide nitrogen.	Dicyano-diamide nitrogen.	Urea nitrogen.	Total.	Cyanamide nitrogen.	Dicyano-diamide nitrogen.	Urea nitrogen.	Total.
1	1·11	10·67	1·14	12·92	1·11	10·62	1·21	12·94
2	0·86	10·16	1·96	12·98	0·86	9·94	1·89	12·69
3	0·86	10·31	1·27	12·44	0·86	10·22	1·29	12·37
4	0·77	10·49	1·59	12·85	0·77	10·51	1·62	12·90
5	1·12	10·44	0·96	12·52	1·12	10·46	1·00	12·58
6	13·25	1·76	0·45	15·46	13·25	1·80	0·4	15·45

Further research showed that the formation of dicyanodiamide-silver complexes is not limited to picric acid. The reaction is typical of all nitrophenols which are soluble in water. Compounds of the silver salts of dinitrophenol, trinitroresorcinol, and trinitrocresol with one and two mols. of dicyanodiamide have been isolated; of these, trinitroresorcinol (styphnic acid) seems to give a more nearly quantitative precipitation and better results than picric acid.

Odda, Norway.

NOTE ON THE DETERMINATION OF UREA IN FERTILISERS.

BY ERLING B. JOHNSON.

The method used in this laboratory for the determination of urea in fertilisers and fertiliser mixtures depends on the well-known fact that urea forms a characteristic, slightly soluble salt with oxalic acid. By using the necessary precautions the solubility of the oxalate can be made so small that a quantitative determination is possible. The following method was developed: 2—5 g. of the dried sample containing urea is extracted with 100 c.c. of anhydrous amyl alcohol, 25—50 c.c. of the filtrate is treated with an equal volume of ether, and the urea precipitated as oxalate by the addition of 25 c.c. of a freshly prepared 10% solution of anhydrous oxalic acid in amyl alcohol. The vessel is stirred and allowed to stand in cold water for half an hour and the precipitate collected on a Gooch crucible, washed first with a mixture of equal volumes of amyl alcohol and ether, and then with ether alone, the volume used in each case being about one and a half times the capacity of the crucible. The precipitate is dried in a vacuum desiccator and weighed. It contains 26·67% of nitrogen and 57·01% of urea according to the formula $H_2C_2O_4,2CO(NH_2)_2$.

The appended table shows the necessary corrections as regards solubility:—

Urea found. g.	Percentage of actual amount present.
0·005	90
0·01	92·8
0·02	95·2
0·04	97·5
0·05	98
0·08	98·8

In some cases the urea is present as a salt or in complexes such as $Ca(NO_3)_2,4CO(NH_2)_2$, in which form it does not dissolve completely in amyl alcohol. In such cases the urea must be liberated.

It is important that the reagents and samples used should be as free from water as possible.

Odda, Norway.

NOTE ON THE ESSENTIAL OIL FROM THE LEAVES OF SKIMMIA LAUREOLA.

BY JOHN LIONEL SIMONSEN.

Skimmia laureola, Hook. f., is an extremely aromatic evergreen shrub which grows throughout the temperate Himalayas from Murree to Mishmi and Khasia Hills. It is also a common undershrub in the Dun Hills. The oil obtained by the steam distillation of the leaves was found to consist mainly of *l*-linalyl acetate, whilst in addition a hydrocarbon, *l*-linalool, and a complex mixture of sesquiterpene alcohols and esters were isolated.

Experimental.

The oil used in these experiments was obtained by the distillation in steam of the shade-dried leaves, a steam pressure of 25 lb. being maintained during the distillation. The yield of oil averaged about 0·5% on the dry leaves.* The oil, which was pale emerald green in colour, had the following constants:—Sp. gr. at 30°/30° 0·9041, n_D^{30} = 1·4648, acid value 3·63, saponification value 197·96, saponification value after acetylation 238·6.†

After washing with dilute alkali to remove the traces of free acid present, the oil was fractionated under diminished pressure (200 mm.), when the following fractions were obtained:—145°—160°, 18·5%; 160°—165°, 5·7%; 165°—175°, 38·6%; 175°—180°, 7·3%; 180°—190°, 9·4%; 190°—240°, 13·8%; loss and residue (by difference), 6·7%. The fractions distilling above 175° C. were all more or less deeply coloured, the colour varying from emerald-green to deep indigo-blue. The higher boiling fractions also showed a beautiful blue fluorescence, but careful tests indicated the absence of methyl anthranilate.

On further prolonged fractional distillation under diminished pressure (200 mm.) the following fractions were ultimately isolated:—(I) 130°—140°, 0·46%; (II) 140°—145°, 4·6%; (III) 145°—150°, 0·61%; (IV) 150°—155°, 8·4%; (V) 155°—160°, 2·3%; (VI) 160°—167°, 2·0; (VII) 167°—173°, 50%; (VIII) 173°—177°, 0·61%; (IX) 177°—182°, 1·05%; (X) 182°—190°, 1·2%; (XI) above 190°, 18·2%.

Fractions I, II, and III appeared to consist essentially of a hydrocarbon. On redistillation a

* The yield of oil and also the ester content varied considerably with the time of collection. Leaves collected in the Chakrata Division during June and early July gave the above mentioned yield of oil, whilst those collected at the end of July and early August contained a much lower percentage of oil. On the other hand, a sample of leaves collected in the middle of August gave a yield of 1% of oil.

† Prior to acetylation the oil was mixed with turpentine as recommended by Boulez (Bull. Soc. Chim., 1907, 4, I., 117).

considerable fraction was obtained boiling at 130°—135° (200 mm.) and at 176°—182° (695 mm.). Analysis gave C=85·5, H=11·6%, whilst the following constants were observed:—Sp. gr. (30°/30°) 0·859, n_D^{30}=1·471, $[\alpha]_D^{30}$=−4·11. The boiling point suggested that the hydrocarbon consisted largely of terpinene, but attempts to confirm this were unsuccessful. Treatment with sodium nitrite and acetic acid in petroleum solution resulted in the production of only the merest trace of a nitrosite, which separated in fine needles melting indefinitely at about 130°; too little was, however, obtained for recrystallisation and analysis. When oxidised with potassium permanganate in ice-cold solution in the usual manner no trace of erythritol or αα′-dihydroxy-α-methyl-α′-isopropyladipic acid was isolated. The nature of the hydrocarbon present in the oil must therefore for the present remain undecided.

Fraction IV consisted of nearly pure *l*-linalool, since on treatment with phenyl isocyanate in the usual manner an excellent yield of linalyl phenylurethane, m.p. 65° C., was obtained.

Fractions V and VI were found to be a mixture of *l*-linalool and *l*-linalyl acetate. After hydrolysis with alcoholic potassium hydroxide an oil was obtained which boiled constantly at 150°—152° (200 mm.) and showed all the properties of linalool. Acetic acid was isolated from the alkaline solution.

Fraction VII, which comprised the bulk of the oil, distilled mainly at 112° (20 mm.), and had the following constants:—Sp. gr. (30°/30°) 0·892, n_D^{30}=1·4537, $[\alpha]_D^{30}$=−7·25°. (Found C=73·9, H=10·1; calc. C=73·5, H=10·2%.) This fraction was pure *l*-linalyl acetate, as shown by hydrolysis, when *l*-linalool and acetic acid were obtained.

Fraction VIII gave on analysis C=74·4, H=10·0%, and was evidently nearly pure linalyl acetate. This was confirmed by hydrolysis when linalool and acetic acid were obtained.

Fraction IX, like fraction VIII, also consisted essentially of linalyl acetate. On hydrolysis linalool contaminated with a trace of a high-boiling alcohol and acetic acid were obtained.

Fraction X was not analysed. On hydrolysis it yielded acetic acid and a mixture of linalool and a high-boiling alcohol. The latter was not obtained in sufficient quantity for examination.

Fraction XI, boiling above 190° (200 mm.), was repeatedly distilled at 43 mm., but no constant boiling fraction could be isolated. Analyses of the various fractions, which were all deeply coloured, showed a carbon content varying from 76·1 to 81·0% and a hydrogen content varying from 10·3 to 11·2%. No more satisfactory results were obtained after hydrolysis of the various fractions, and further investigation of the somewhat unpleasant smelling oils was abandoned.

In conclusion the author wishes to thank Mr. Puran Singh for placing the results of the preliminary experiments at his disposal, and his assistant, Mr. T. P. Ghose, for making most of the analyses.

NOTE ON THE PRODUCTION AND TESTING OF ZIRCONIA.

BY W. R. SCHOELLER, PH.D.

Several of the processes which have been proposed for extracting zirconia from Brazilian ore are based on the precipitation of zirconium as a basic sulphate (*cf.* Rossiter and Sanders; J., 1921, 70 T). The chief aim of these processes is the elimination of iron, generally without regard to the simultaneous removal of any titanium present. Thus, Rossiter and Sanders' method, though shown to effect a quantitative precipitation of zirconia free from iron, admittedly fails to eliminate titania. This is not surprising, considering the readiness with which titanium sulphate is hydrolysed in a hot, feebly acid solution. It is remarkable, however, that the Brazilian ore experimented upon by Rossiter and Sanders was found to contain only "traces of titanium," and this statement may convey an erroneous impression that the ore from the Brazilian deposits is almost free from titania. Analyses of samples representing large shipments proved titanium to be a regular constituent of the Brazilian ore in quantities varying from 0·6 to 1·2%. The principal constituents of six samples are given in Table 1; the analyses were carried out according to the method of Powell and Schoeller (Analyst, 1919, 44, 397; J., 1920, 67 A). Small amounts of lime and magnesia were also present.

TABLE 1.

	A.	B.	C.	D.	E.	F.
ZrO_2	79·58	77·47	76·18	68·82	56·56	53·50

	99·34	95·95	99·60	99·57	99·28	96·82

n.d.=not determined.

Titanium and all other impurities found in the ore are, however, completely removed in the process based on the preparation of crystallised zirconium oxychloride. This process is seldom mentioned in English technical literature, probably because it is more expensive than a precipitation process; further, the oxychloride mother-liquor is fairly rich in zirconium, part of which is not recoverable in the pure state, because a solution heavily charged with impurities will not crystallise; but the operation is a simple one, and can be made to yield chemically pure zirconia.

It occurred to the author that the economics of a combined oxychloride-basic sulphate process might repay investigation, and the following suggestions for a process embodying Rossiter and Sanders' work are put forward tentatively. The finely ground ore is fused with sodium carbonate (*cf.* U.S. Pat. 1,261,948; J., 1918, 339 A), which the author considers superior to caustic soda because a better decomposition of the zircon in the ore is effected at the higher temperature required to melt the charge. The melt is leached 2 or 3 times with hot water, the volume of the first leach liquor being adjusted so as to deposit sodium carbonate crystals on cooling; the recovered alkali is available partly for neutralisation, and partly for opening up a fresh charge of ore. The insoluble residue is treated with the zirconium oxychloride wash-liquors and part of its mother-liquor, the solution evaporated to dryness, and the mass extracted with hot water. The filtered liquid is concentrated somewhat, mixed with hydrochloric acid, and left to crystallise; the crystals are filtered off by suction and washed with cold hydrochloric acid (1:1) till the washings are colourless. Instead of converting the oxychloride into zirconia by precipitation with ammonia and ignition of the hydroxide, the crystals may be heated in porcelain or silica vessels until the water and acid are expelled; the dry residue is powdered, boiled with dilute ammonia, filtered off and strongly ignited,

giving pure zirconia. The acid used in washing the oxychloride is mixed with a certain proportion of the oxychloride mother-liquor and used for dissolving the next batch of leached fusion residue; the balance of the mother-liquid—sufficient to prevent undue accumulation of impurities—is withdrawn from the circuit, neutralised with recovered sodium carbonate, and precipitated with sulphurous and sulphuric acids according to Rossiter and Sanders' process. The last operation yields the remainder of the zirconia practically free from iron and alumina, but contaminated with titania; this oxide is probably quite pure enough for certain industrial purposes (*e.g.*, as a pigment). Further experimental work based on fractional solution or precipitation will probably indicate a method for eliminating the titania.

Examination of commercial zirconia.

To judge from the results of analyses of zirconia made by the author, the efforts of British manufacturers to produce a pure oxide have not so far been attended with success. The composition of the samples indicated that the ore had been opened up by fusion with nitre cake: the material was found to be strongly contaminated with arsenic pentoxide, no doubt derived from nitre cake obtained from impure sulphuric acid. The presence of arsenic is highly objectionable, especially where the zirconia is intended for use in X-ray work or as an opacifier in enamelling cooking utensils; it is liable to be overlooked unless a special test is made. For its detection and determination, 2 g. of zirconia is fused with 15—20 g. of sodium carbonate in a platinum crucible, the melt is leached with hot water, the solution filtered, acidified with hydrochloric acid, and saturated with hydrogen sulphide. To expedite the precipitation of the arsenic sulphide, the acidified filtrate may be first digested on a water-bath with potassium iodide, which reduces the arsenic acid. The sulphide is filtered off, evaporated with sulphuric acid until fumes are evolved, the liquid made alkaline with bicarbonate and titrated with iodine solution.

Table 2 shows the impurities found in three samples of zirconia of British manufacture.

TABLE 2.

	(1).	(2).	(3).
SiO_2	1·28	0·76	0·64
TiO_2	1·45	0·98	1·70
Al_2O_3	0·16	0·30	0·13
Fe_2O_3	0·36	0·34	0·28
As_2O_5	1·03	1.37	1·30
SO_3	0·16	1·85	1·94

In addition to the above constituents, the author has detected other impurities or added ingredients in specimens of zirconia obtained from abroad; viz., lime, soda, fluorine, chlorine, carbon dioxide, and boron trioxide. The analysis of zirconia must be made on the unignited sample, as the loss on ignition represents sulphur trioxide, carbon dioxide, fluorine, and chlorine, if present, as well as moisture or combined water.

London Section.

Meeting held at Burlington House on May 2, 1921.

MR. JULIAN L. BAKER IN THE CHAIR.

THERMAL LOSSES IN THE GAS PRODUCER PROCESS.

BY N. E. RAMBUSH.

The object of the present paper is to elucidate the principles by means of which it is possible to determine with a reasonable degree of accuracy the thermal efficiency of the gasification of a given fuel without large-scale tests, and generally to emphasise the relative importance of the various causes of thermal losses to engineers and chemists concerned with the working and design of gas-producer plants.

There are many types of gas-producers on the market, and within limits, it would be more or less right to say that producer-gas can be made in practically any apparatus. The object of this paper is not to discuss the advantages or disadvantages of any of the many producer types available, but it will be assumed that a gas-producer is employed which is suitable for dealing with the particular fuel and purpose under consideration.

Gas-producers and plants may be divided into two main groups:—

(1) *The hot gas-producer* in which the gas made is consumed in the same hot crude state in which it leaves the producer.

(2) *The cold gas-producer*, to which gas cooling and cleaning plant is attached to enable the gas to be supplied cold and of a degree of cleanliness that corresponds to the application in question. This group may again be divided into two subsections according to whether by-products are recovered or not.

The points having a bearing upon the thermal efficiency of the gas-producer process are:—(1) Moisture content in fuel, (2) nature of volatile matter in fuel, (3) grading of fuel, (4) soot formation, (5) ash content of fuel, (6) the radiation and convection heat losses from the producer proper to the atmosphere, (7) gas leakage losses, (8) losses in washing liquors, (9) moisture content in gas, (10) the temperature of and sensible heat contained in the hot gas leaving the producer.

Before dealing with these various points I should like to make clear the basis upon which I have determined the thermal efficiencies and losses. I have come to the conclusion that the best standard from the point of view of the gas-producer technologist is the ratio between the net heating value and volume at N.T.P. of the gas evolved per unit weight of theoretically dry fuel and the net heating value of the said unit weight of theoretically dry fuel. For plants in which the tar and oils are recovered as a valuable by-product and not considered a nuisance in the gas-making process, it might be argued that the heating value of the tar obtained (which can be utilised as fuel) should be added to that of the gas. Since the tar (especially on a by-product plant) may have a larger value to the industry than that corresponding to its heating value, I have refrained from doing so. On the other hand, it appears undesirable to complicate still further the matter of calculating the thermal efficiency of the gas-producer process by making allowances for the fuel required to raise the steam for the air blast, and create the power required for driving the auxiliary machinery, since this involves factors entirely outside the proper process of gas making.

1. *Effect of moisture content in fuel.*—Most good-class bituminous fuels have such a low moisture content that the evaporation of this small amount of moisture has very little effect upon the thermal efficiency of the gas-producer process; but for such high-moisture fuel as wet coke breeze, and especially some peats or lignites, the moisture content will have a very great effect.

This may be demonstrated by the example of the gasification of a peat having a moisture content of 50% and a net heating value of 4000 Cals. per kg. (7200 B.Th.U. per lb.) of theoretically dry substance. For each kg. of dry substance of such peat introduced into the producer 1 kg. of water would have to be evaporated and heated to the gas outlet temperature of, say, 150° C.

Supposing now the peat instead of being introduced in a wet state were introduced in a moisture-free state into a by-product recovery producer, and the gas volume (at N.T.P.) and average specific heat of the gas evolved be approximately 2·5 cb. m. per kg. and 0·3 Cal. per cb. m., respectively, also that the gas outlet temperature be about 500° C., then the sensible heat in or the thermal capacity of the gas from 1 kg. of dry peat between 150° and 500° C. would be $2{\cdot}5 \times 0{\cdot}3 \times (500-150) = 262$ Cals.

Now the heat required to raise 1 kg. of water to 100° C., evaporate it and superheat the steam to 150° C. will be 652 Cals., so that there is a deficit of $652-262$ Cals. (=390 Cals.) per kg. of dry fuel, which must be supplied by burning a part of the fuel itself (roughly 10%) in the lower part of the producer, with a consequent reduction in the heating value of the gas and the thermal efficiency.

If the fuel bed is not deep enough to enable the sensible heat of the gas generated in the lower part to be utilised for the evaporation of the moisture, the thermal loss will of course be still higher, but the above remarks will indicate quite clearly why wet peat gasifications in the past have often met with so little success.

Returning now to the effect of the moisture content upon the thermal efficiency of the gas-producer process, it is obvious that before being able to estimate accurately the effect of evaporating the moisture it would be necessary to determine the difference in the gas outlet temperatures theoretically when using a dry and a moist fuel. Such determination could only be made by those practically experienced in this work, and even then may be liable to considerable error if the particular gas-producer design is not borne in mind.

As the object is to find what may reasonably be expected as to thermal efficiency, it is suggested that the heat required for bringing the moisture content to 100° C. and evaporating it be taken as having to be supplied from the heating value of the dry fuel only, while the heat required for superheating the steam thus raised is assumed to come from the sensible heat of the gas. Under this assumption the decrease in thermal efficiency obtainable in practice due to moisture will always be smaller than the thus estimated figures.

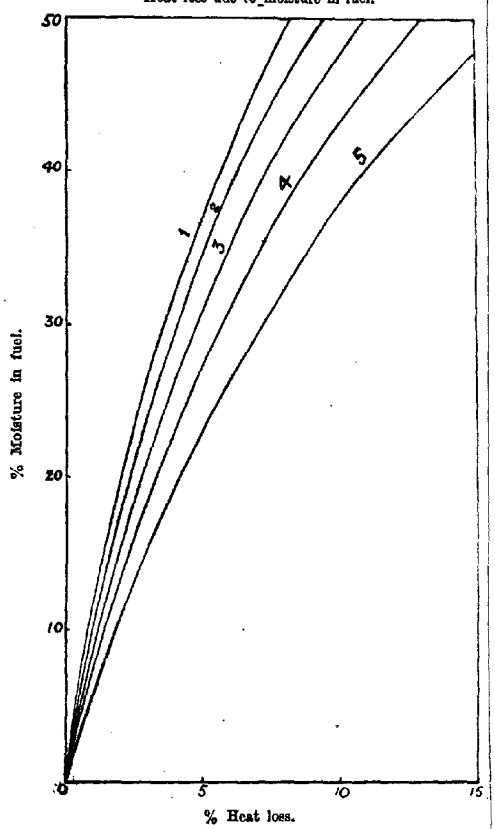
The curves in Fig. 1 show the reduction in the percentage of the thermal efficiency for fuels of varying heating value and different moisture content, estimated in this manner.

2. *Effect of volatile matter in fuel.*—Since the percentage of volatile constituents in fuels used for gas production varies from, say, 1% (on coke and anthracite) to above 80% (for woods), it is difficult to predict from the ordinary methods of ultimate gas analysis how much of this volatile matter will be obtained as gas or tar, unless of course the same material had been treated in a gas-producer before.

For the above reasons I decided about 12 months

ago to alter the method of fuel investigation in our laboratory at Stockton-on-Tees. The method I instituted is, generally speaking, to subject a small quantity of the fuel to a retorting test under temperature conditions approaching those obtained when treating the fuel in a by-product producer.

Heat loss due to moisture in fuel.



1. 8000 Cals. per kg. (14,400 B.Th.U. per lb.).
2. 7000 „ „ (12,600 „ „).

4. 5000 „ „ (9000 „ „).
5. 4000 „ „ (7200 „ „).

FIG. 1.

So far a reasonably close agreement has been found between the quality and quantity of the volatile matter obtained as tar in our special distillation test apparatus and that obtained in practice, excepting that the tar obtained in practice seems to have a higher average boiling point and is always obtained in a slightly smaller quantity. Probably some decomposition of the lighter oil constituents of the tar takes place in the producer. Our fuel testing method and its bearing upon the results to be obtained in practice is not yet completely established, but in another six months or so it is hoped to publish laboratory results, and also to show comparisons between these and the results obtained in practical operation with the same fuel.

As certain fuels in properly designed by-product producers may yield a very large quantity of tar, and as this tar per unit weight may have double the heating value of the fuel treated, a retorting test is, in my opinion, the best method by which to determine the "tar value" of a producer. Even if this should yield a slightly higher quantity of tar than is obtainable in practice, the laboratory results will indicate a slightly lower thermal gasification efficiency than actual operation, and incidentally is far cheaper to carry out than a large-scale commercial test.

To arrive at the net heating value of a fuel from its ultimate analysis, all the oxygen is commonly assumed to be combined with the hydrogen. This is not so, since in practice substances like acetic acid, phenols, etc., are often obtained in the tar and liquors on a gas-producer plant, thus indicating the presence of carbon-oxygen links as well as hydroxyl groups in the fuel. For this reason, and since heat may be required inside the fuel itself to liberate its various particles, it is clear that a calorimeter determination, deducting the latent heat of the steam formed by the combustion of all the hydrogen of the fuel, be used as the measure for the net heating value instead of a net heating value arrived at from the ultimate fuel analysis.

3. *Effect of fuel grading.*—The grading of the fuel is a most important factor, not only from the point of view of the solid fuel particles that may be carried away by the gas (as dust), but also from the point of view of the output of the producer and the gas quality.

With fuels containing an excessive quantity of fines the dust loss may be serious unless preventive provision is made in the design. With the same grading of the fuel the loss is obviously a function of the gas velocity in the outlet pipe. Since the dust-carrying power of a gas alters with the sixth power of the velocity it is obvious that the best means to prevent thermal loss on this account is to have the crude gas as it leaves the producer as cold as practicable, or to provide large dust settling spaces (say a roomy space above the top level of the fuel bed).

To obtain the same gas analysis and output from fuels of various grading in a producer of the same diameter it is necessary to alter the fuel depth, or alternatively to provide that depth of fuel bed which is the most economical for the worst conditions of grading.

I have had communicated to me privately the following results of tests made in reference to this matter.

Fuel.	Grading.	Economical depth.
Coke	¾ in.—1¼ in. cubes	2 ft. 6 in.
	1¼ in.—2 in. cubes	3 ft. 9 in.
	2 in.—3 in. cubes	5 ft. 10 in.
Coal	1 in. nuts	1 ft. 10 in.
Coal	Run of mine	4 ft. 10 in.—6 ft. 6 in.

Analyses of the fuel and of the gas are not given. It is, however, not surprising to find that the more uneven the grading and the larger the biggest pieces of fuel, the greater must be the fuel depth for efficient gasification.

It should be borne in mind that certain fuels (in particular some lignites) break up and crumble shortly after introduction into the producer, so that a larger dust loss will be obtained in practice than might be expected from the grading test carried out on the fuel in its natural state.

Other aspects to be considered, quite apart from the gas-producer process in itself, are the losses such as may be incurred (due to wind) by storing a slack fuel containing a large quantity of fines in the open or handling it in an unprotected fuel-conveying plant. Gas producer users will be well advised to have their fuel and storage plant protected against atmospheric effects, not only from the point of view of dust loss, but also on account of the moisture added to the fuel on rainy days.

4. *Soot formation.*—This varies with the type of fuel used, but it is caused by the tarry matters evolved from the coal being exposed to such a high

temperature inside the producer that they are decomposed into gas and carbon (soot). Soot formation is practically absent in some by-product producers where the only decomposition of tar which takes place is into gas and oils of a higher boiling point; but even with hot gas producers soot formation can be reduced considerably by feeding or distributing the fuel evenly over the top of the fuel bed, especially if the latter be not too shallow.

Thermal loss by dust and soot formation.—As is obvious this will vary considerably, but tests carried out several years ago on some large by-product producer plants working with rough slack as fuel indicate that this loss may be as high as 3% of the heating value of the fuel. With the latest designs of by-product producer plant it is reduced to a very much lower figure.

5. *Effect of ash.*—The three main factors in connexion with the ash which have a bearing upon the gasification process are:—(*a*) the composition of the mineral matter in the fuel; (*b*) the sensible heat lost in the hot ashes; (*c*) the loss due to unburnt carbon in the ash.

(*a*) Except for the work by J. T. Dunn (J., 1918, 5 T) I am not aware that any considerable work has been done in reference to the fusing temperatures of ash from various English coals, although a large amount of work has been done both by the U.S. Bureau of Mines on American fuels and by the University of Zürich on Continental fuels. Until more extensive research has been carried out it will not be possible to point out in advance what quantities of steam would be the most advantageous to use or whether the producer should be water-jacketed or not, etc., in gasifying fuels of various qualities of ash. I shall therefore not go into the details of the extensive subject of ash fusibility, but only point out one or two other points of interest to the gas-producer technologist.

If the mineral matter in the fuel is not completely oxidised, extra oxygen is required from the air blast to complete the oxidation, with a consequent dilution of the resulting producer gas by nitrogen.

On the other hand, the ash may contain compounds which partly volatilise on heating up (say carbonates), also with dilution of the gas as a consequent result. Discrepancies in some fuel analyses are often due to similar causes.

(*b*) The sensible heat contained in the hot ashes leaving the producer varies with the ash content of the fuel, but is not of any consequence in a water-luted producer, because the heat is utilised practically completely to raise steam (by diffusion) and to preheat the air blast, but even with a "dry bottom" producer this heat loss is very small. Assuming the temperature of the ashes leaving the producer to be 100° C. and 400° C. for wet and dry bottom producers respectively, and assuming that 20% of the coal is removed as ash (sp. heat 0·3) the total sensible heat in the ash per kg. of fuel will be 6 Cals. and 24 Cals. and the loss of heating value of fuel (6700 Cals. per kg.) will be 0·09% and 0·36% respectively.

(*c*) The thermal loss due to incompletely burnt fuel varies, apart from the skill of the operator, with the heating value and the ash content of the fuel.

The figures in the following table give the approximate thermal loss due to this cause for several assumed conditions.

It is generally found in practice that the higher the ash content in the fuel, the higher will be the carbon content in the ashes; hence the ash loss is of the cumulative order in regard to the ash content.

It will probably be agreed that with bituminous coals containing up to 15% of ash it is possible to maintain the carbon content in the ash at or below 10%, which means that the thermal loss will not be more than 2·05% of the heating value of the fuel.

The carbon loss in % on the fuel used is calculated by the formula $X = ac/(100-c)$, where X is the carbon lost in percentage on fuel used, a the ash content of the fuel, and c the carbon content of the ash.

	Carbon content of ash. %	Lb. of carbon lost per 100 lb. of fuel gasified, *i.e.*, % carbon loss.	Thermal loss on heating value. %
Fuel, 10% ash,	10	1·1	1·33
12,000 B.T.U./lb.	15	1·8	2·17
or 6700 Cals./kg.	20	2·5	3·02
Fuel, 20% ash,	12	2·7	3·66
10,700 B.T.U./lb.	18	4·4	5·92
5950 Cals./kg. ..	25	6·7	9·08
Fuel 30% ash,	15	5·3	8·08
9500 B.T.U./lb.	22	8·4	12·85
5280 Cals./kg. ..	30	12·9	19·70

Fig. 2 has been prepared to cover the possible conditions met with in practice. Given a fuel of a certain ash content, and knowing the carbon content in the ashes, the thermal loss in terms of percentage on the net heating value of the fuel is at once obtainable.

6. *Radiation and convection loss.*—To obtain a more definite idea as to the order of the radiation and convection loss from the outside shell of a producer, I measured in 1918 the "skin" temperature of a 10-ft. by-product recovery gas-producer under full load conditions and found that the temperature 4 ft. from ground level was 69° C.; 6 ft., 85°; 8 ft., 101°; 10 ft., 109°; 12 ft., 92°; 14 ft., 79°; 16 ft., 76° C. The producer was 20 ft. high and the grate level was at 5 ft. 6 in. and fuel level 13 ft. from ground level. Thus the producer in question had an average skin temperature of about 80° C., while the total exposed surface was about 84 sq. m. Assuming for exposure to average atmospheric conditions a total radiation and convection loss of 760 Cals. per sq. m. per hour, we get a total loss of 63,000 Cals. per hour. The producer in question gasified about 850 kg. of coal per hour at 6700 Cals. net heating value per kg., hence the loss was equivalent to 1·1% of the heating value of the fuel. The producer in question had an exposed surface unnecessarily large in reference to its diameter, the exposed surface of many producers of the same or larger throughput, especially where no by-product recovery is aimed at, being only about 45—50 sq. m., with a corresponding decrease in the radiation etc. loss.

The radiation and convection loss from the outside casing of most gas producers to the atmosphere will be independent of the rate of gasification and represents a practically constant hourly loss proportionate to the total exposed surface.

Judging from the above practical observations as to the "skin" temperature and when using good class bituminous fuel, I consider that for the larger producer capacities (working at not less than ¾ load) the radiation and convection loss should not exceed 1% of the heating value of the fuel gasified per unit of time.

7. *Losses due to leakage* may be subdivided into (*a*) periodical loss due to poking and cleaning, (*b*) continuous loss due to leaky joints.

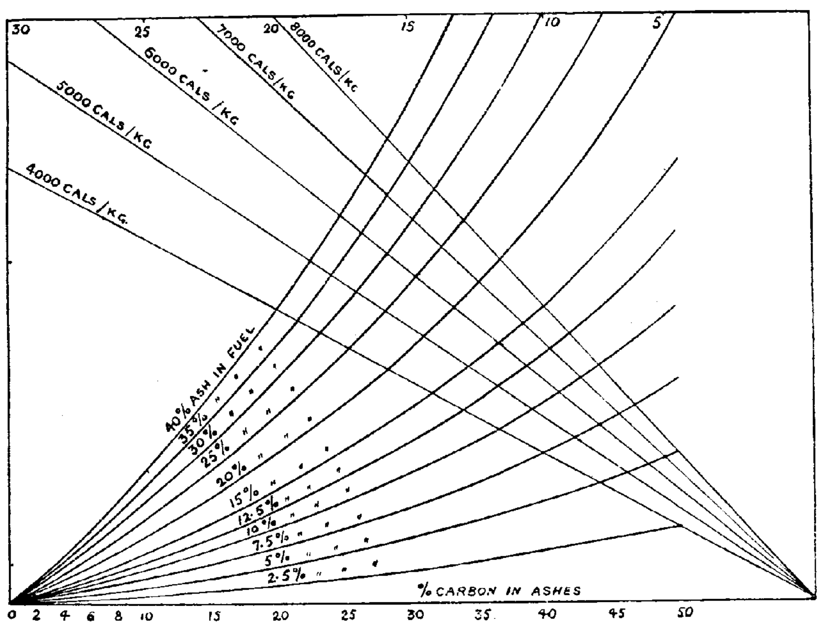
(*a*) Assuming a 2-in. hole be open on the top of a producer having a gas outlet temperature of 500° C., then the corresponding hourly loss will be 3000 cb. ft. when the gas pressure is 2 in. and 10,000 cb. ft. when the pressure is 20 in. These gas volumes correspond to cold and clean gas. Many poking and cleaning holes are larger than 2 in. On many static producers a man will occupy on an average about one-tenth of his time poking the fuel bed of a producer, hence the thermal loss may easily

be 0·5% of the fuel gasified. Of course, on producers having mechanical stirring and ashing means this loss is practically eliminated. Cleaning of mains during operation should be avoided as far as possible, and mains should be arranged vertically or inclined so that they are as "self-cleaning" as possible.

(*b*) Leaky joints such as are caused by faulty manufacture or vibration (due to wind, machinery, etc.) exist even on the best plants. Even on such carefully laid pipe lines as for town gas supply it has been proved that leakages may be 1% of the gas supplied. Of course, the loss will depend on the surface of the plant exposed to the atmosphere, and and thus escapes to the atmosphere. The loss can be reduced, but its existence can be observed on any gas-washing plant by watching the behaviour of the washing liquid leaving a tower. If an inverted bottle filled with water is placed below the water level and close to the water outlet pipe in the tank, gas will soon rise in the bottle, replacing the liquid. From a test made by me on one of the early types of combined air saturator and gas cooler on a Lymn plant (by estimating the CO_2 content in the air entering and leaving) the gas loss due to this cause was estimated at over 0·5%.

(*b*) All gases dissolve in water, and also some of the tar oil compounds are soluble, particularly the

% of heat loss due to carbon in ash.



C in ashes. † Ash in fuel. → Cals./kg. † Heat loss.

FIG. 2.

is obviously largest on cold gas producer plants. This type of loss becomes larger with cleaner gas, but smaller with lower pressure difference between the gas and the atmosphere.

It is obvious that the plant which works with the lowest possible pressure difference between the gas and the atmosphere will have the smallest leakage loss; thus if the whole plant were under suction this loss would disappear. For obvious reasons it is always advisable to have the gas under pressure at any points where poking or cleaning is required during operation. This pressure difference, however, should be maintained, automatically if possible, at the lowest limit.

Assuming average conditions I do not think that the leakage loss on a cold gas producer plant should be assessed at less than 1% of the heating value of the fuel gasified.

8. *Loss in gas cleaning and cooling plants.*—The losses on this account may be divided into two subheadings, viz., (*a*) substances mechanically carried away by and (*b*) matters dissolved in the washing liquid.

(*a*) An appreciable quantity of gas is carried away mechanically with the washing liquors leaving the cooling, cleaning, absorbing, etc. towers tar acids or phenols. The loss occurring in this respect, so far as the gaseous substances are concerned, is not very large and cannot be avoided; but by carefully controlling the waste liquors of the plant and the cooling water system, the phenols can be recovered. It is not impossible to obtain an effluent containing up to 0·5% of these phenols, which effluent can be economically treated. There are, however, many gas-producer plants in existence, where by exercising a little care and slightly modifying the working cycle of the plant the phenols can be recovered, instead of being run into the sewers.

Summarising the matter of the thermal losses due to gas carried away by the washing liquors, I do not think that even with a well-designed plant this should be considered less than 1% of the heating value of the fuel treated.

9. *Content of water vapour in hot crude gas.*—This originates from three sources: (*a*) That amount of the steam admitted with the air-blast which is not decomposed in the producer; (*b*) the amount due to "moisture content" of fuel; (*c*) the amount due to "water of decomposition" of fuel.

As to (*a*), the following figures, given partly in the two papers by Bone and Wheeler (Proc. Iron and Steel Inst., 1907 and 1908) and partly arrived

at in my own experience, will give a general guide as to the amount of steam decomposed in the gas-producing process when using bituminous fuels:—

Depth of fuel bed ..	3 ft. 6 in.			7 ft.					7 ft. 6 in.	12 ft.
Temp. of air blast, °C.	50	55	60	60	65	70	75	80	85	78
Lb. of steam per lb. of coal	0·21	0·33	0·45	0·45	0·56	0·80	1·1	1·55	2·5	1·45
% steam decomposed	95	100	76	87·4	80	61·4	52	40	30	62
Lb. of steam decomposed per lb. of fuel	0·2	0·33	0·34	0·39	0·45	0·49	0·57	0·62	0·75	0·90

It will be obvious that the deeper the fuel-bed the more complete is the steam dissociation. So far as the steam-carbon reaction is concerned it is obvious that the time factor plays a rôle.

I have further come to the conclusion that if by suitable modifications it is possible to increase the gasification capacity of a producer for the same fuel (such as by introducing mechanical stirring means), it is advisable at the same time to increase the fuel depth if a good quality gas is to be maintained.

Speaking broadly, and quite apart from the softening effect of the steam upon the clinker formation, the most economical blast temperature, from a thermal point of view, is that which corresponds to a practically complete dissociation of all the steam supplied with the air-blast. It has been calculated (see Richards, "Metallurgical Calculations") that the decomposition of about ¼ lb. of steam per lb. of bituminous coal will counterbalance the exothermal reactions caused by the formation of the carbon dioxide usually present in gas obtained in ordinary hot gas producer work. It will be noticed that the calculated figure practically agrees with those quoted as results of ordinary practice.

From the point of view of the thermal efficiency of the gas-producer only (quite apart from the heat required to raise steam), it is obvious that the more undecomposed steam remaining in the crude gas, the larger will be the thermal loss due to the sensible heat in such undecomposed steam, which leaves at the same temperature as the gas. This rule holds good in spite of the fact that the gas temperature will be lower, the higher the percentage of undecomposed steam.

In connexion with the use of steam as the endothermal agent in the gas-producer process, reference may be made to a suggestion put forward many times in the past thirty years or more—namely, to introduce products of combustion instead of steam with the air-blast for the purpose of saving in the steam consumption. From the calculation below, showing the steam saving that can be effected at a certain reduction in the heating value of the gas, it will be clear why the experiments in this respect have been fruitless, and the gas in many cases useless for industrial work.

Assume that with the addition of steam *only* to the air-blast the following operating conditions are obtained:—Steam per kg. coal, 1·5 kg. (78° blast temp.); gas per kg. coal, 3·5 cb. m. (N.T.P.); heating value of gas, 1370 cals. per cb. m. (154 B.Th.U. per cb. ft.) net. Then steam per cb. m. of gas= 0·43 kg.

When adding products of combustion, assume that they have the composition: 18% CO_2, 82% inerts. Now assume that it is permissible to reduce the heating value of the gas by 20% (from 155 to 124 B.Th.U. per cb. ft.), due to the introduction into the gas of nitrogen from the products of combustion. This means that if all the CO_2 is decomposed we can add per cb. m. cold gas: $20\times100/82=24{\cdot}4\%$ or 0·244 cb. m. of products of combustion.

The weight of carbon dioxide of this volume is: $0{\cdot}244\times18\div100\times1{\cdot}964=0{\cdot}086$ kg.

The relative endothermal effects of steam or carbon dioxide on hot carbon are as follows:—

$$C+CO_2\rightarrow2\,CO-38{,}800\ \text{Cals.}$$
$$C+H_2O\rightarrow CO+H_2-28{,}800\ \text{Cals.}$$

—*i.e.*, the endothermal effect of 1 kg. of carbon dioxide is equivalent to that from $3{\cdot}88\times18\div(2{\cdot}88\times44)=0{\cdot}55$ kg. of steam. Therefore the addition of 0·244 cb. m. of products of combustion to the air-blast will replace $0{\cdot}086\times0{\cdot}55=0{\cdot}0473$ kg. of steam.

In other words, the above rough calculation shows that by reducing the heating value by 20% the saving in steam is only 11% when using 1·5 lb. of steam per lb. of coal.

The calculation takes no account of the fact that the sensible heat loss incurred by cooling the hot gas is practically proportional to the volume of the hot gas, hence when adding products of combustion with a consequent larger gas production per unit of fuel the thermal gasification efficiency will certainly be less than with steam as the endothermal agent.

When the trouble involved in handling products of combustion is borne in mind, it is obvious that only disadvantages are to be looked for, unless perhaps the future enables us to use a gas richer in carbon dioxide.

As to the moisture content in the hot gas due to moisture in fuel and water of decomposition, both of these can be judged from the laboratory examination of the fuel, it being practically certain that none of the "moisture" in the fuel will be decomposed by the reaction with the carbon in an up-draught type of gas producer.

10. *Effect of gas outlet temperatures and sensible heat loss.*—If a good class bituminous coal is used the following gas composition and outlet temperatures may be reasonably expected:—

	Hot gas producer.	Cold gas producer.	
		Without recovery.	With ammonia recovery.
Gas analysis:

Temp. of hot gas ..	950° C.	700° C.	550° C.
Net latent heat of gas at N.T.P.			
B.Th.U. per cb. ft.	165·9	156·7	142·3
Cals. per cb. m. ..	1476·6	1394·5	1266·5
Thermal capacity per cb. m. gas N.T.P. in Cals.	329	264	290

In calculating the thermal capacity of the gas (total sensible heat) I have used the figures given

by Holborn and Henning for diatomic gases, steam, and carbon dioxide, and by Langen for methane. Fig. 3 has been drawn (completed early in 1918) upon which thermal capacity per cb. m. (N.T.P.) of each gas has been plotted against the temperature. In the above figures for sensible heat in gas any sensible heat contained in tar, dust, and soot has been eliminated, as the thermal loss due to these will be very small in comparison with the heat loss in the gas. The carbon and hydrogen losses from these three sources are of another order and have been dealt with under their separate headings.

Thermal capacity in Cals. per metre³ (N.T.P.) between 0° and T° C. at constant atmospheric pressure.

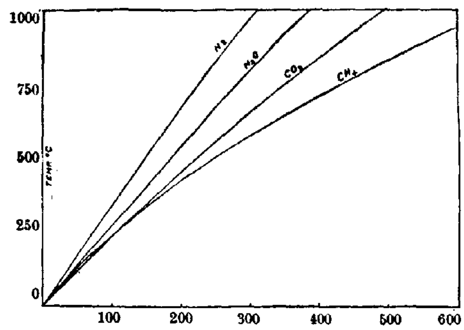

FIG. 3.

Sensible heat in hot gases.

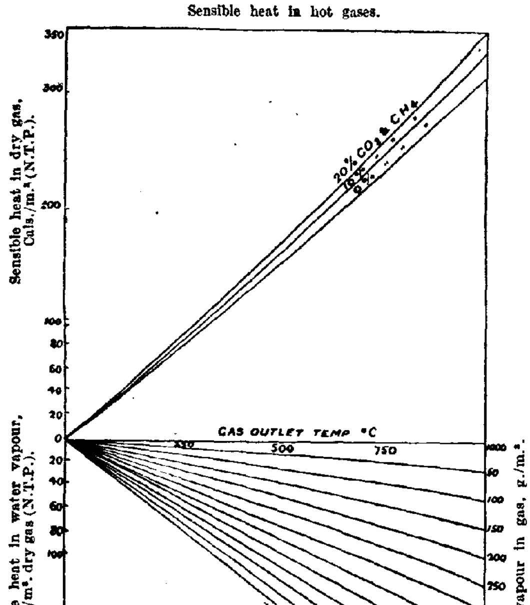

FIG. 4.

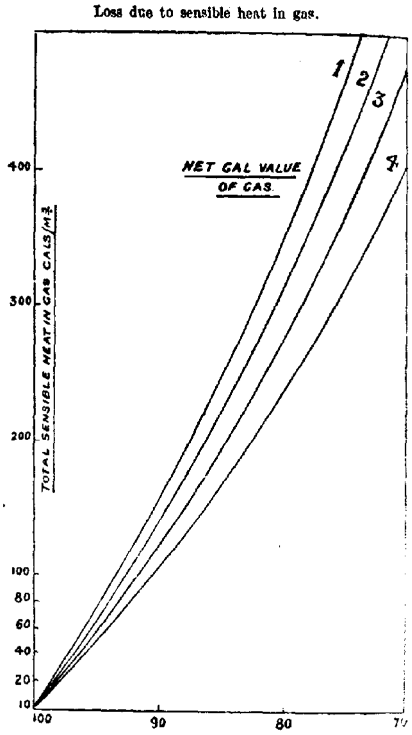
It will be seen from the summary table at the conclusion of this paper that in the three cases the thermal loss due to the sensible heat in the hot gases leaving the producer represent:—(1) 17%; (2a) 14%; (2b) 16% of the calorific value of the fuel; therefore the sensible heat loss is the chief among all the losses of the cold gas producers. The only means available for utilising such heat is either to obtain a lower gas outlet temperature with a gas richer in heating value, or to utilise the heat for other purposes, *e.g.*, to raise the steam required in the process by cooling the gas, either (1) directly by washing the air blast for the producers with the hot water from the gas cooling plant, or (2) indirectly by raising steam or heating water in boilers or vaporisers.

Loss due to sensible heat in gas.



% latent heat.

2. 1250 „ „ (140·4 „ „).
3. 1100 „ „ (123·5 „ „).
4. 950 „ „ (106·7 „ „).

FIG. 5.

But even for the hot gas producers the loss of sensible heat in the gas may be of consequence if the furnaces are not placed close to the producers, and although it may be an advantage to have a high carbon monoxide content from a heating process point of view, it is often more economical from a thermal point of view to increase the hydrogen content somewhat at the expense of the carbon monoxide content, thus decreasing the outlet temperature and thereby radiation losses, while the difference in sensible heat for the two outlet temperatures will be present as the latent heat of the hydrogen in the gas.

It should therefore be emphasised that the gas composition is not always a measure of a thermally efficient hot gas producer plant unless the loss in gas temperature between gas producer and furnace is borne in mind.

All the above remarks are only generally applicable to an average English bituminous producer coal, but the gas composition, gas outlet temperatures, and moisture content in gas will vary

considerably with the various kinds of fuel gasified (from wood waste, wet peat, and town refuse to anthracite).

For this reason I have prepared Fig. 4 on which the sensible heat (thermal capacity) per cb. m. (N.T.P.) of gas of varying composition and of the accompanying moisture content can be directly determined for various gas outlet temperatures. Seeing that the methane content is generally less than the carbon dioxide content, and its specific heat not very different from that of this gas and the rest of the components of producer gas (all diatomic gases), the diagram should prove of practical utility even if a small error is caused by assuming the specific heat of methane to be the same as that of carbon dioxide. I have also assumed that the relative specific heats of the various gases do not alter if the gases are mixed together.

* This calculation is made only for comparison, and the loss only exists in practice in a degree corresponding to the difference in the gas temperature at furnace and leaving producer.

It may have been noted that all the losses in the gasification process, except the sensible heat loss, can be expressed in terms of the net heating value of the fuel. As, however, it is easier to express the sensible heat loss in terms of that contained per unit volume (at N.T.P.) of cold gas, it will be necessary when determining the expected thermal efficiency first to assess all the other losses, thus giving as a deficit that heat which must exist as sensible heat in the hot gas and as latent heat in the cold gas. When the ratio between the net available latent heat in the cold gas and the total sensible and latent heat in the hot gas is calculated, the sensible heat loss in terms of the calorific value of the fuel, and therefore the net gasification efficiency, can be obtained (see Fig. 5).

General use of above statement.—Following are some examples of how the above statements may be applied for calculating the thermal gasification efficiency of various types of fuel and plant. The figures and assumptions are given in the serial order in which they are best determined.

As regards cases 3, 4, and 5 the actual thermal efficiencies obtained in practice were:—(3) 70·2; (4) 74·5; (5) 76·5. The figure in case 3 represents a yearly average of data on coals used and gas metered, while case 4 represents a 288 hours' continuous test and case 5 a one-month test.

The discrepancies between theory and practice of the three cases are of so small an order that the method of calculation put forward is in my opinion sufficiently reliable for general adoption—perhaps in certain cases with an additional factor of safety.

In conclusion I wish to express by thanks to the Directors of The Power-Gas Corporation, Stockton-on-Tees, for their kindness in permitting me to publish results obtained by my firm, and also to Mr. A. T. Grisenthwaite, B.Sc., for help given in working out the curves and table appended hereto.

Discussion.

Captain C. J. Goodwin asked as to the possibility of utilising a small quantity of oxygen for enriching the air supply to producers. It would increase the temperature considerably and tend to fuse the ash, but he thought there was the possibility of obtaining improved results.

Dr. M. W. Travers said that he had been working at the heat balance of the steam-blown gas-producer (*cf.* J. Soc. Glass Tech. 1921). From experience in connexion with the glass industry with modern gas-producers, from which the gas issued at a temperature of not over 700° C., it did not appear that soot was actually formed in the producer. The gas as it issued from the producer was loaded with tar fog, but the actual formation of soot appear to be, at least in some measure, due to the reversal of the CO_2—C—CO reaction in contact with the dust. In speaking of the velocity of the gas issuing from the producer he presumed that the author referred to the velocity of the gas in the top layer of the fuel bed. Some interesting work on the nature of the fuel bed, the resistance to the flow of the gas, and the nature and grading of the fuel had been carried out by the U.S. Bureau of Mines (Tech. Paper 137, p. 57). He had been unable to find any information in technical literature which would enable him to connect the chemical and thermal properties of tar, which was certainly endothermic. In one of the latest publications on the subject, the Report of the Research Committee of the Institution of Gas Engineers, it was assumed that the heat of formation of the tar could be calculated from the composition of the tar, on the assumption that the heat of formation was equivalent to that of naphthalene. Mr. Rambush had determined the heat of combustion of the tar, and a few analyses of his material would provide the necessary information.

Mr. P. Parrish said that the author gave the thermal efficiency of a coke breeze gas-producer plant as 66·3% where cold gas had to be utilised; did he regard it as more advantageous to adopt the gasification of coke breeze in conjunction with a Bonecourt boiler for the production of steam in lieu of ordinary steam production in a Lancashire boiler using a forced draught furnace for coke breeze? In the latter case an efficiency of 58—60% was certainly possible. The cost of the plant, *i.e.*, the producer for gasifying coke breeze and the provision of a Bonecourt boiler for an installation capable of dealing with 750 gallons per hour, would be something of the order of £6000, whereas a Lancashire boiler with a chimney shaft to deal with 750 gallons per hour would cost £3000. The theoretical efficiency which the author would lead one to expect was 66·3%, and that higher efficiency entailed an extra expenditure of £3000 for 750 gallons per hour. Did he consider that to be a commercial proposition which would justify embarking on the gasification of coke breeze in a producer in conjunction with a Bonecourt boiler, in comparison with the forced draught type of Lancashire boiler, which was in operation to such a large extent to-day? Again, he doubted whether it was possible economically to gasify coke breeze by itself. It had been tried at the Birmingham gas works for a long period, but it had been found necessary to mix 50% of producer coal to get satisfactory results. Moreover, in view of the flame temperature of the cold producer gas, it was found that some form of regeneration was necessary to get the best effect.

Mr. Arthur H. Lymn said that he had carried out a large number of large-scale tests during the last twenty years, and had seldom known them to come nearer the actual regular figures of later works practice than did the figures which the author had given. Consequently the author's anticipated results seemed so near the actual results of works practice that they not merely anticipated the figures of large-scale tests, but practically eliminated the necessity for them. The efficiency of the producer should include the steam that went into it, although in those cases where other apparatus was included with the producer, such as washing plant, it was always possible to recover that steam from the waste heat of the gases. Nevertheless he would like to see the figures in the paper also shown on the basis of including the steam. In dealing with the heat contained in the gas from hot gas-producers as compared with the recovery gas, the author had taken certain temperatures of the outgoing gases from the producer. His own opinion, from a wide experience, was that 900° C. was scarcely a fair figure for hot gas-producers; it should not be more than 700°, and where the author spoke of 17% in comparison with 14% losses for different types of plant, that would probably change this to 12 or 13%, but it would be well if they could have the calculations for an outgoing temperature of 700° also, because a well-conducted hot gas-producer should not have a higher temperature than that. The author had drawn attention to the determination of the fusibility of ashes. He (the speaker) suggested that some institution in this country should undertake a systematic investigation of the fusibility of fuel ashes, as had been done by Constam for German fuels some years ago.

Dr. R. Lessing agreed that the fusibility of ashes was one of the most important points in running gas-producers. The fusibility of the ash in a coal sample need not be exactly the same as that obtained when working on a large scale, because in the latter case they were not dealing with a finely powdered and homogeneous sample. In some samples of ashes of mixed fuels consisting of cannels and coals there was a large lump of refractory cannel ash enveloped in fused coal ash which had

held up the whole fuel charge and led to trouble. In that case a properly prepared sample would have shown a very high degree of refractoriness, but not fusibility. He had adopted a plan of carrying out ash analyses on an extensive scale by which it was possible to predict the clinker formation in a particular fuel charge with a high degree of accuracy.

Professor J. W. COBB wrote that any reliable process which enabled the individual losses incurred in producer-gas practice to be gauged with an approximation to truth from a laboratory examination of the fuel would serve a useful purpose. The loss due to sensible heat in gases leaving the producer was due to the carriage of heat upwards by the products of gasification of the fixed carbon in the bottom of the producer, and its incomplete extraction in the distillation process at the top; if, as now seemed likely, it became possible to replace air in many cases by oxygen in gasification owing to the cheapening of oxygen which was being brought about, the absence of nitrogen in large volume would tend to lessen that loss. Other accompanying economies would also increase efficiencies so far that some items of loss inevitably remaining would assume a greater importance relative to the total loss than had been the case in the past. One of these was the loss by radiation and convection, which had usually found a place in an omnibus item, termed "radiation, convection, etc.," and was made responsible for leakage, unknown losses, and the avoidable and unavoidable errors of experiment. He was interested therefore in the author's observations and calculations under this head. His figure of 1% for a large producer under at least three-quarters load confirmed the one which Mr. Hodsman and himself had felt justified (from the substantial agreement of three methods of calculation) in using when estimating the probable losses of an oxygen gasification process.

Dr. J. H. PATERSON wrote that from a theoretical point of view the losses which took place during the artificial cooling of the gas produced had little interest. On the other hand, data showing the relationship between gas outlet temperature and rate of combustion and thickness of fuel bed would add very considerably to our somewhat scanty knowledge of these subjects. Of great value also would be curves showing the effect of fuel bed thickness and rate of working on the unaltered water content of the gas, and also on the hydrogen content.

Mr. RAMBUSH, in reply, said that it was possible to design a gas-producer to use oxygen or air enriched with oxygen; probably it might mean a producer in which the ash was tapped out as molten slag, because (unless endothermal agents were added to a large extent) the heat would be far more intense in the lower zones. Investigations on the relative effect of steam and oxygen in the gasfication process were still in hand. He had not been able to determine the heat required for liberating the tarry matter from the fuel, but considered it to be of a small order, since the fall in temperature of the gases between the lower and upper part of the producer would account for this splitting up; in other words, if there were no volatile matters to be driven off, the gas outlet temperatures would be still higher than those used in the tables in his paper. The amount of dust removed depended upon the velocity in the gas outlet pipe; if the velocity in the gas outlet pipe became lower due to the removal of a smaller volume of gas per unit of time, it would become lower in the upper parts of the fuel bed as well as in the gas space above. With regard to the efficiency calculated for the gasification of coke breeze, he had chosen as typical a coke breeze containing 30% of ash although he had gasified successfully coke ballast containing up to 45% ash. By careful working the ash loss might be made less than the 10% assumed as an illustration, but whether such a coke breeze could be burnt more efficiently on a boiler grate he could not say. The coke breeze gas producer plant at the Birmingham Gas Works was designed for using coal, but as there was a superproduction of coke breeze to be burned somewhere, it was burnt with the coal in the gas producers. Dr. Lessing had mentioned the clinker formation when using mixed fuels. His experience was that the use of mixed fuels often caused such difficulties and his advice was not to mix different fuels if the best efficiency were aimed at. In his opinion there was still more work to be done on the relative fusing temperatures of ashes from various coals, such as had been commenced by Dr. Dunn. The temperature of the outgoing gases was very important and depended upon many factors especially upon the depth of fuel bed and the quantity of steam that was being added to the air blast. He had seen gas producers with temperatures as high as 900° and others of 700° C.

In reply to Dr. Paterson's remarks, the losses that took place by artificial cooling were of great importance as they emphasized that a thermally economical cold gas producer must be so designed as to give a crude gas leaving the producer, which retained as sensible heat as little as possible of the heat of the solid fuel. The further data required in reference to depth of fuel bed in reference to all factors to be considered in the working of a gas producer plant were very difficult to put down in definite figures, unless given in reference to a given fuel of constant quality and grading.

Regarding Prof. Cobb's remarks there was a limit to the completeness of the extraction of heat from the hot gases leaving the producer and that limit depended either upon what one could afford to spend in the construction of the gas producer, or upon the possibility of gasifying the particular coal at very low temperatures. The present state of the industry did not enable one to lay down any definite rule in this respect.

Glasgow Section.

Meeting held on February 22, 1921.

MR. J. H. YOUNG IN THE CHAIR.

LEAD CORROSION WITH RELATION TO SULPHURIC ACID MANUFACTURE.

BY WM. G. M^cKELLAR.

In the manufacture of sulphuric acid by the chamber process, frequent troubles are encountered owing to the failure of the lead sheets used in constructing the chambers, and an attempt has been made to ascertain the most suitable quality of lead for the purpose. Two types of desilverised lead are in general use for building chambers, namely, Pattinsonian and Parkes; each brand is advocated by the various refiners, and every maker guarantees that his lead is at least of 99·9% purity.

In the past Parkes's lead has often been regarded with suspicion, and generally for chamber building it has been blamed, I believe, by most chamber constructors, who prefer to use Pattinsonian lead; but in spite of preferences for one brand of lead or another, the results obtained, measured by years of service, out of any particular chamber or set of chambers are very unsatisfactory, and the reasons for failure most obscure.

It should be noted that while the problems relating to lead in chambers seem to be ever-recurring, trouble seldom occurs with lead used

in Glover towers, cisterns, gas flues, and pumping pipes. Lead used in these situations usually appears to be immune from the troubles which beset chamber lead.

When the conditions of chamber working are surveyed, the following points are seen to deserve attention.

Method of supporting the leaden sheet.—Some builders prefer to hang the sheets from the top rail of the chamber frame and have no cross rails in the structure; the leaden sheets are secured to the vertical posts simply by clinching or folding over the end of the strap round the section of the post. Now while this form of construction has the merit that it provides very efficiently for expansion and contraction due to changes of temperature, it creates a difficulty which does not seem to have been sufficiently appreciated, arising from the fact that the sheet at the point of suspension is in a state of stress due to the weight so carried, which stress is a maximum at the point of suspension, reaching zero at the bottom of the sheet; a sheet so hung (when the chamber is at work) has its interior surface attacked by a corrosive atmosphere, accompanied by a relatively high temperature, 100°—180° F. (38°—82° C.), and these three sets of conditions, namely, stress and corrosion with high temperature, acting at the same time, appear capable of producing disastrous results in a very short time. Fig. 1 shows a strip cut from a sheet in a chamber, the entire lead work of

Top. Middle. Bottom.

Lead sheet, showing aggravated corrosion at top of sheet.

FIG. 1.

which failed or gave way after a much shorter time than it should have done; the sheet is badly pitted, the pits being deepest and more marked at the top and disappearing towards the bottom. Analysis in such a case is useless, and even micrographical examination failed to disclose any difference in structure likely to cause this failure. The immunity from attack by sulphuric acid enjoyed by lead is probably due to the formation of an insoluble lead sulphate, and it can easily be conceived that if a protecting skin on lead once formed is subject to a continuous stretching action the skin will never be allowed to adhere, but will become detached as quickly as formed; further, the continuous stretching action exposes fresh lead surfaces to the action of the gases, and these surfaces are probably very susceptible to the action of the acid gases. There is therefore some reason in favour of modifying our views regarding this form of chamber construction. The alternative system of cross rails raises difficulties due to timber being an excellent non-conductor and not allowing sufficient heat radiation from the lead skin, and notwithstanding all the devices which have been proposed for helping to get the heat away, much yet remains to be done to perfect the cross-rail system. Further, the cross-rails prevent the free circulation of air around the chamber sheets, which is most desirable, and there is a lack of flexibility in the provisions for expansion. In any system in which timber is in contact with lead work, the life of a leaden chamber is greatly lessened at these points of contact.

Chamber ventilation.—In any chamber plant working under normal conditions, there is always a large amount of energy in the form of heat due to the reaction between the sulphur dioxide and oxygen, which must be dissipated either by natural ventilation or by artificial cooling by water sprays on the outside of the lead work. Water cooling can be and is carried out satisfactorily, although this method involves an extra charge; but where there is no such arrangement, it is necessary to depend on the access of a free circulation of air round about the lead work. In the past this problem has not had adequate attention. In too many cases the passages are unduly restricted, due no doubt to the desire on the part of the builder to get as large an internal capacity as possible; in the west of Scotland the very wet climate is also a contributory cause. The passages are roofed in, thus imprisoning much heat that could easily be spared and tending to shorten the life of an acid chamber. In the years when lead cost £12 or less per ton, I believe it would have paid manufacturers to floor the chamber passages with lead, allowing free ventilation for the chamber sides and ends by dispensing with passage roofs.

Efficiency of nitre recovery.—With no system of nitre recovery, the quantity of sodium nitrate used would amount to 11% on the sulphur charged, but by the introduction of the Gay-Lussac tower this figure was reduced, till to-day over the United Kingdom it might average 3½%; on certain plants figures as low as 1¾% are claimed, and with close supervision and adequate gas scrubbing plant there is no doubt this low figure can be obtained over a continuous period of months. A low nitre consumption or loss leads to an increased life in a chamber plant, and the reason is not difficult to find. If sodium nitrate is "potted" or ammonia oxidised, nitric acid is formed, and this enters the chambers and attacks the lead work, whereas if the nitrosulphonic acid is decomposed by mixing with weak acid, and the mixture run down the Glover tower, either N_2O_4 or N_2O_3 is formed, both of which are excellent carriers of oxygen without the vicious properties of nitric acid.

Supply of water vapour.—The regular and well-distributed supply of water vapour, either in the shape of water sprays or steam, is essential. If the supply is insufficient, the strength of the acid mist in a chamber may rise dangerously, and a set of conditions exist which cause serious destruction of the lead work. On the other hand, if the supply is in excess, equally serious damage may be done to the lead work, accompanied by a greatly increased loss of nitrous compounds.

For all the four factors dealt with above as having an influence on the life of a sulphuric acid chamber, the chamber management alone is responsible; factors which merit the attention of the lead maker will now be considered.

Speed of sheet lead rolling.—The work of the Corrosion Committee of the Institute of Metals has shown that the cracking of brass condenser tubes is due to the state of internal stress produced in drawing them out; in fact any form of stamped or cold-drawn brass work is unreliable because of the abuse it has received in the process of manufacture, and in the light of a failure of lead, to be described it is evident that lead also can receive such abuse on rolling that it never recovers. It may be said that lead anneals at ordinary temperatures; but while this may be generally taken as correct, it would seem that there are cases in which the lead has been so severely treated that it did not recover even after the lapse of years. The particular failure to which reference is made happened both at our St. Rollox factory and in that of one o

our neighbours. A large number of leaden boxes were made for the purpose of sending sulphuric acid abroad; the lead was $\frac{1}{16}$ inch thick and weighed 5 lb. per sq. ft. Each box carried 198 lb. of acid, and there was 7% clearance space to allow for any gas that might be given off after filling. The boxes were protected by an outside casing of wood, and all the joints were autogenously welded by means of the air and hydrogen flame. A small filling hole was cut out of the roofs of the boxes, and after filling the boxes were finally sealed by welding as before, a period of two days elapsing between the filling and final sealing, so as to allow of any gas generated to escape. The boxes lay in the warehouse for seven days preparatory to shipping, and about 3% developed leaks in a most alarming fashion. On examination of the defective cases it was found that numerous cracks had been formed in the lead, through which the acid flowed. The lead was exceedingly brittle, and a moderate blow with the fist on a defective side of a box caused the lead to give way with an irregular fracture, and left a hole which resembled the hole left in a glass pane when broken with a stone. There was no swelling of the lead work, so that it was evident that the lead had not been stressed by internal pressure. The lead was brittle and broke off short when bent in any direction. Exhaustive analyses showed that the lead was 99·9%.

It was evident that some means other than analysis was required to assist in clearing up lead problems, and accordingly I have endeavoured to inaugurate micrographic work for this purpose.

Naturally a lead maker wants to run his mill at the highest possible speed so as to get the highest output per unit of power and other charges involved, but care should be taken that the sheet of metal so produced has not received serious injury in the rolling process. Where cost is immaterial, certain architects insist on cast lead for roof work, and it is alleged that such cast lead is very superior to any form of rolled lead.

The presence of lead oxide inclusions in the mass of the metal is another source of failure, and these account, I believe, for the failures which take place in new leaden sheets in a chamber when first put to work. The failure takes the form of minute circular perforations which soon develop into large holes, and sheets having this defect never have a satisfactory life.

Attempt to solve the problem of lead corrosion.—Some fifteen years ago it was stated that lead containing about 0·1% of copper, either resulting from the presence of copper in the ores or introduced into the molten lead, resisted the action of the gases in a sulphuric acid chamber excellently. I regarded this very much as a quack remedy, and microscopical examination confirmed this, but in order to test the question along other lines four sample strips were prepared as follows:—

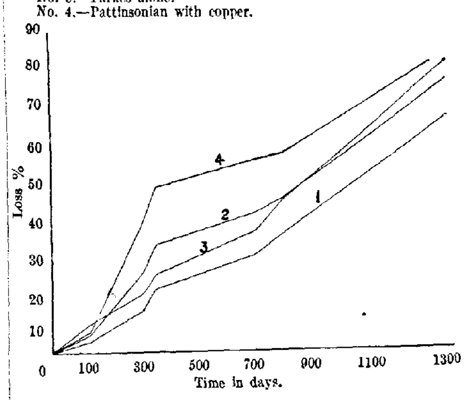
	No. 1. Zinc-treated lead with copper.	No. 2. Pure Pattinsonian.	No. 3. Zinc-treated lead.	No. 4. Pattinsonian with copper.
	%	%	%	%
Pb (diff.)	99·9029	99·9897	99·9719	99·9142
Cu ..	0·0790	0·0005	0·0017	0·0780
Bi ..	0·0120	0·0004	0·0170	0·0006
Sb ..	0·0005	0·0017	0·0008	0·0012
As ..	0·0009	0·0009	0·0017	0·0008
Sn ..	0·0022	0·0028	0·0030	0·0025
Fe ..	0·0003	0·0017	0·0003	0·0007
Mn ..	Nil	Nil	Nil	Nil
Ni ..	Nil	Ft. trace	Nil	0·0004
Zn ..	0·0020	0·0020	0·0034	0·0015
Ag ..	0·0002	0·0003	0·0002	0·0001

The strips measured $10\frac{1}{4}'' \times 3''$, and were hung facing the travel of the gases by leaden hooks in the centre of a second chamber in a set for varying periods of time, and the losses in weight noted. The experiment lasted in all 1270 working days; at the conclusion the pieces had the following composition:—

	1.	2.	3.	4.
	%	%	%	%
Pb (diff.)	99·8966	99·9796	99·9647	99·9021
Cu ..	0·0550	0·0010	0·0004	0·0660
Bi ..	0·0400	0·0110	0·0260	0·0255
Sb ..	0·0030	0·0018	0·0024	0·0019
As ..	0·0009	0·0004	0·0008	Trace.
Sn ..	0·0020	0·0031	0·0036	0·0025
Fe ..	0·0003	0·0012	0·0003	0·0006
Mn ..	Nil	Nil	Nil	Nil
Ni ..	Nil	Nil	Nil	Ft. trace.
Zn ..	0·0020	0·0017	0·0016	0·0013
Ag ..	0·0002	0·0002	0·0002	0·0001

Unfortunately the analysis failed to throw any light on the problem, and the appearance of the pieces did not produce any evidence of value in determining the factors which regulated corrosion. The losses which occurred are shown in the following table and graph. The curves show to some extent the value of the clean, polished surface of the new

No. 1.—Parkes with copper.
No. 2.—Pattinsonian.
No. 3.—Parkes alone.
No. 4.—Pattinsonian with copper.



Time, days.	% Loss.

288	11·30	21·7	16·2	35·4
328	17·34	29·34	21·44	45·24
649	26·28	37·99	32·87	53·10
734	31·63	41·66	41·34	54·61
1270	64·69	74·72	79·86	82·21

lead in resisting attack, and also illustrate the protective value of the lead sulphate formed on the lead as indicated by the increased rise in the curve after cleansing at short intervals.

These curves also raise the query "if the addition of copper was of value in the case of lead No. 1, why was it not equally valuable in the case of No. 4?"

Some time after the test had been running it was evident that it would have been of great advantage if there had been four parallel samples under test, which were only weighed at the conclusion of the experiment, and the disturbing effect of washing eliminated, but the test had reached such a stage that this could not be done for want of sufficient sample material to work on.

Micrographs were made of all four samples. The samples were cut with a sharp joiner's chisel, washed with methylated spirit to remove grease and dirt, immersed in cold 10% nitric acid, and the lead nitrate removed at frequent intervals by means of a camel-hair swab brush. The etching occupied about 3—4 days.

Parkes lead (copper-treated).
× 12.

FIG. 2.

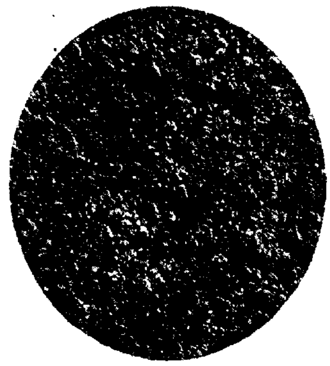
It was found later on that the samples cleaned by spirit were often twisted and uneven, and as it was not desirable to flatten them out with a blow, they were planed true with a Stanley plane and then etched. A sample of copper-treated lead shows no outward indication of the presence of copper, but if it is etched the copper speedily appears as large segregates, which are apparently capable of causing a good deal of harm. Fig. 2 shows a sample of Parkes lead (copper-treated, ×12) etched by 1/1 nitric acid vapour, and reveals a deep pit with a large copper segregate, the deep black stain being due to a very dense segregate and the lighter shaded marks to less dense segregates.

Pattinsonian lead, copper-treated.
× 80.

FIG. 3.

Fig. 3 shows a sample of Pattinsonian copper-treated lead (×80) etched with 10% nitric acid; the black network showing all through is due to streaks and prills of copper. When 10% nitric acid is used for etching it is very difficult to keep the copper from disappearing, but by etching with the vapour from 50% nitric acid the copper is not nearly so severely attacked; unfortunately lead recrystallises at about 90° C., so that the vapour method of etching is of no use in examining the general lead structure.

From Figs. 4—7, showing the four sample pieces etched with 10% nitric acid, it is evident that the addition of copper to lead causes a very marked reduction in the size of the crystals. This may, however, be due to the violent plunging the lead



Zinc-treated lead, with copper.
× 26.

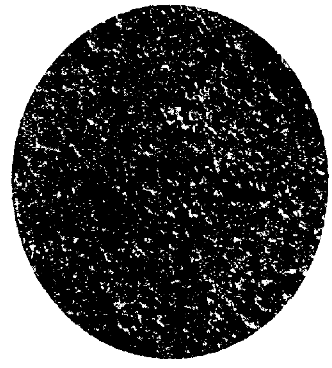
FIG. 4.

receives after the copper is added, and not to the presence of copper at all.

Conclusions.—Summing up what has been said, the following points emerge:—

Wastage and destruction of lead in chamber work arise from faults which may readily creep in during the course of acid production, and it is for the makers of sulphuric acid to reduce these chances to the minimum.

Equally, trouble will arise with lead owing to the treatment it may have received at the rolling mills, and it falls on the lead makers to consider carefully this, and to disabuse their minds of the belief that notwithstanding the treatment lead may receive it will always anneal and recover at ordinary temperatures.



Pure Pattinsonian lead.
× 26.

FIG. 5.

Analysis alone is of no value in disclosing the source of trouble in lead, but if used in conjunction with micrographic work progress would be made.

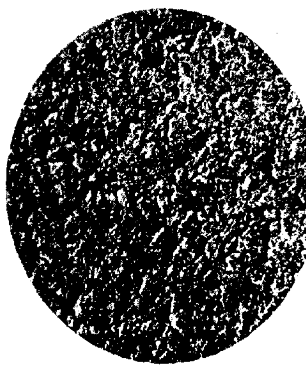
I am satisfied that there is no alloy of copper with lead at the end of the scale where lead predominates, or in other words, it is not possible to produce a solid solution of copper in lead.

The vagaries as between the results obtained with Parkes and Pattinsonian lead which have been treated with copper lead to the conclusion that the protective value of the copper is mythical. There might be some value in treating the lead at the last stage of refining with a proportion of liquid copper, which, after thorough stirring through the molten charge, should be allowed to settle off. It should not be poured along with the lead. In this case the copper might act beneficially as a scour by alloying

Zinc-treated lead.
× 26.

FIG. 6.

itself with certain prejudicial metals which are likely to be present with the lead, but great care would be required to see that all the copper was actually settled out, otherwise in the atmosphere of an acid chamber there is every probability that destructive galvanic action would be set up by the presence of the copper.



Pattinsonian lead, with copper.
× 26.

FIG. 7.

Experience with plant actually built with copper-treated lead has so far shown it to have a shorter lifetime than a similar quality of untreated lead.

All our experiments and observations, so far, still incline us to favour the use of Pattinsonian lead against Parkes, and as zinc is insoluble in lead, the presence of any zinc accidentally left in after separation of silver would be quite as detrimental as that observed in the case of copper, with this difference, that, owing to the copper being readily seen, it is much easier to see when mischief has been caused by that metal than it would be in the case of zinc, which cannot be so readily detected by micro-examination.

Communications.

THE RELATION BETWEEN THE DENSITY AND COMPOSITION OF GLASSES.

BY W. L. BAILLIE.

Prior to the researches of Winkelmann and Schott (Winkelmann, Ann. Phys. Chem., 1893, **49**, 401; 1897, 67, 105; Winkelmann and Schott, *loc. cit.*, 1894, **51**, 697, 731) little appears to have been definitely known regarding the relations existing between the composition of glasses and their physical properties. It was shown (*loc. cit.*) from the study of a large number of glasses that many physical constants admit of computation with tolerable accuracy by means of appropriate numerical factors and that, in particular, density may be so calculated. For the majority of the silicate and borosilicate glasses studied, the calculated and observed densities agreed to within 2% or thereby. Larger discrepancies, however, were encountered in the case of zinc borate and lead borate glasses, the greatest being just over 10%.*

The relation between density and composition was investigated later by Tillotson (J. Ind. Eng. Chem., 1911, **3**, 897; 1912, **4**, 820), who proposed considerable modifications in certain of Winkelmann's factors. It was shown from experimental meltings and from data collated from Larsen (Amer. J. Sci., 1909, **28**, 163), Wallace (Z. anorg. Chem., 1909, **63**, 1), Day and Allen (Bull. 31, Carnegie Inst. of Washington) and others, that the new factors so obtained led to distinctly better agreement between calculated and observed values than did the old. Unfortunately, however, Tillotson did not derive factors for PbO (†) and K_2O, two important constituents of many varieties of optical glass. In this respect, therefore, his results are incomplete, and full comparison with other systems of density moduli is not directly possible.

In connexion with the work of the Directorate of Chemical Inspection it became necessary to ascertain the applicability of published moduli to certain types of glassware. Winkelmann's values being found to lead to greater discrepancies between calculated and observed densities than was desirable, an endeavour was made initially to complete Tillotson's series of factors. Consideration of his data, however, led to a distinctly lower value for the density of combined SiO_2, and it became apparent that it would be necessary to evaluate new factors on this basis. Conditions rendered it impossible to prepare suitable series of glasses of known and simple composition. The problem had therefore to be attacked by consideration of published data and determination of the densities of available glasses already analysed.

Subsequent to the completion of this work, English and Turner published two papers on the density of lime-soda and magnesia-soda glasses respectively (J. Soc. Glass Tech., 1920, **4**, 153, 126). They showed that the original factors of Winkelmann and Schott are inadequate, and that Tillotson's factors, although superior, do not satisfactorily reproduce their experimental results. A few factors are tentatively proposed by them, but final pronouncement is delayed pending further work. It is shown, however, that certain results are at variance with Tillotson's deductions from Larsen's data (*loc. cit.*). This anomaly is discussed below.

It is customary to express the composition of glasses in terms of constituent oxides. The calculation and application of density moduli is based on the assumption that to each of these oxides, in

* Adequate summaries of these researches are given, with numerical data, in Hovestadt's "Jena Glass" (Macmillan), 1902, pp. 144 *et seq.*

† See note to Table II.

its combined state, may be assigned a constant, though empirical "density."

Let the analytical results for a glass be $a\%$, $b\%$, $c\%$, ...$n\%$ of the n oxides composing it, and let the sum of the determined constituents be S—a quantity which should differ only slightly from 100. If, now, these oxides have, in their combined states, densities A, B, C ....N, and if the density of the glass, as determined by experiment, be X, then, equating the sum of the partial volumes to the total volume, we have:—

$$\frac{a}{A}+\frac{b}{B}+\frac{c}{C}+\ldots\ldots\ldots+\frac{n}{N}=\frac{S}{X} \quad \ldots\ldots\ldots\ldots (1)$$

Given a suitable series of n glasses of identical qualitative composition, numerical values may be obtained for the n density moduli, A, B, C............N from the n simultaneous equations which are derived. Satisfactory values having been obtained for the commoner constituents, it is comparatively simple to extend the series to include other oxides. The concordance shown below between calculated and observed results is substantial indication of the validity of the basic assumption, but the anomaly mentioned above would appear to indicate that the nature of the remaining oxides may not on occasion be without effect on the density moduli of certain constituents.

Generally, by analogy with liquid mixtures, it is to be expected that the densities calculated for the combined oxides will exceed those observed for the same oxides in the free state. This was stated to hold without exception by Winkelmann and Schott (*loc. cit.*). Tillotson, however, found that Al_2O_3 appears to expand in combination with resulting diminution in density. This observation has been confirmed, and it is shown below that Sb_2O_4 behaves similarly. At this stage it is not possible to express a definite opinion on the significance of these conclusions, but it is suggested that combination of these oxides with silica and bases to form vitreous bodies may be attended with fission of their molecules. The following table shows the difference between the densities of the free and combined oxides, as found by the observers named. In the last column are given the moduli now proposed.

TABLE I.

Densities of glass-forming oxides in free and combined states.

Oxide.	Density in free state.		Density in combined state.		
	Determined.	Remarks.	Winkelmann.	Tillotson.	Proposed.
SiO_2	2·22	Deville 1855	2·3	2·3	2·24
Al_2O_3	3·85	Rammelsberg	4·1	2·75	2·75
Sb_2O_4	6·69	—	—	—	3·00
B_2O_3	1·79	Clarke	1·9	2·24	2·90
As_2O_3	3·74	—	4·1	(4·1)	3·33[1]
ZnO	5·65	Schröder	5·9	5·9	5·94
BaO	5·00	Clarke	7·0	7·0	7·20
CaO	3·30	Moissan	3·3	4·1	4·30
MgO	3·60	Clarke & Moissan	3·8	4·0	3·25[2]
PbO	9·30	Clarke	9·6	9·6	10·30
K_2O	2·66	—	2·8	(2·8)	3·20
Na_2O	2·55	—	2·6	2·8	3·20

[1] Provisional only.
[2] In absence of alkali oxides, the value 4·30 is to be taken.

The analogy with liquid mixtures, which is not invalidated by the behaviour of Al_2O_3 and Sb_2O_4, explains simply the considerable discrepancies recorded by Winkelmann and Schott in the case of the borate glasses, and also the differences now found in the case of the two exceedingly dense flint glasses (Nos. 8 and 9, Table 9). It will be seen that all the markedly exceptional glasses are substantially of the nature of simple borates or silicates. The glasses which show close agreement are invariably of the more usual double silicate, borosilicate, or aluminosilicate types. It would therefore appear that this treatment is, in general, inapplicable to glasses of the simplest composition. Fortunately this reservation is generally of little moment since, in practice, such glasses are only very rarely encountered.

It will be clear from the manner of their derivation that all these moduli are interdependent, so that errors in the values of the moduli for the commonest oxides will be reflected in all deductions based thereon. Since silica is the major component by weight in the majority of glasses, and since its modulus is the smallest, it follows that the partial volume of combined silica is generally the largest in a glass. For these reasons attention was primarily directed to the determination of the density of combined silica, employing data from Tillotson (*loc. cit.*). For reasons discussed below, Winkelmann's data were disregarded.

The method of obtaining these moduli renders it possible to achieve absolute concordance between calculated and observed value for any small series of glasses all containing the same oxides and to the same number as there are glasses in the series—*e.g.*, four glasses containing SiO_2, CaO, Na_2O, and Al_2O_3 in different proportions. This misleading appearance of accuracy must be sacrificed if good general agreement is to be obtained with glasses of widely different compositions. The moduli now proposed have been derived for this more general purpose. Certain causes are considered below which may impair the degree of correlation which may be obtained when many glasses are in question.

It is known that the thermal history of a glass exercises a profound influence upon its physical and mechanical properties. "Rupert's drops" represent a familiar laboratory example, while the "tempered"—more accurately, case-hardened—glass of de la Bastie represents an attempted commercial utilisation of the resistance to impact and sudden changes in temperature shown by glass which has been subjected to appropriate heat treatment. The presence of strains, due to inefficient annealing, has been shown to augment expansibility, to reduce thermal endurance, and to diminish density. In the case of certain MgO—Na_2O—SiO_2 glasses, English and Turner (J. Soc. Glass Tech., 1920, 4, 153) found that careful annealing of air-cooled rods caused increases in density of as much as 0·01. Similar figures have been recorded for window glass (Chevandier de Valdrôme and Wertheim, Comptes rend., 1845). Zulkowski has made the suggestion that "plaining" yields a homogeneous glass primarily because it allows of the attainment of chemical equilibrium in the mass (Chem. Ind., 1900, 23, 108). If this be accepted it follows that faulty heat-treatment during founding may occasion discrepancies between observed and calculated densities which annealing cannot eliminate.

Tillotson has rightly insisted that the densities attributed to the (combined) constituent oxides of glasses must be regarded as controlled by more than the density of the uncombined oxides alone. The general order of the moduli would appear to indicate that the density of the free oxide is a controlling factor. On the other hand, it is yet to be proved that mode of combination is without effect. Indeed, the anomalous behaviour of MgO, described later, suggests that this factor is occasionally of considerable importance.

The duplex character of the "plaining" process premised by Zulkowski (*loc. cit.*) leads to the conclusion that during the process some at least of the oxides must alter their state of combination till equilibrium is reached. Up to this point no constant modulus may be applicable. It is conceivable,

indeed, that "plaining" may not entirely correct this, so that, depending on the qualitative and quantitative composition of the glass, application of any rigid modulus may lead to imperfect concordance between calculated and observed results. On the other hand, it appears hardly likely that considerable differences can exist between the moduli appropriate to the various states of combination, so that the differences between calculated and observed results should be, in all probability, of the order of 1—2%. This conclusion is borne out in the case of MgO, the only oxide which, so far, has been found to show any variation in modulus with mode of combination. In the case of experimental melts it is comparatively simple to carry "plaining" to the required degree, and in such cases agreement between calculated and observed results should be close. Optical glasses, on the other hand, do not always admit of such prolonged heating, and for this reason less rigorous agreement may not unreasonably be expected. It is noteworthy, in this connexion, that not only is this state of affairs realised in the data below, but that marked divergencies between calculated and observed densities in the case of glasses of extreme composition are generally negative, *i.e.*, the calculated densities are high.

The effect of permissible analytical errors upon the calculated densities may be shown generally as under:—

Let the true composition of a glass be $a\%$, $b\%$, $c\%$.........$n\%$ respectively of its n constituents. Then—

$$\frac{a}{A}+\frac{b}{B}+\frac{c}{C}+\dots\dots\dots+\frac{n}{N}=\frac{100}{X} \quad\dots\dots\dots\dots \quad (2)$$

If, now, the analytical results be in error by amounts α, β, γ.........ν, then the calculated density, X_1, is given by

$$\frac{a+\alpha}{A}+\frac{b+\beta}{B}+\frac{c+\gamma}{C}+\dots+\frac{n+\nu}{N}=\frac{100+\alpha+\beta+\dots+\nu}{X_1} \dots (3)$$

Rewriting and substituting from (2), we have

$$\frac{100}{X}+\Sigma\left(\frac{\alpha}{A}\right)=\frac{100+\Sigma(\alpha)}{X_1} \quad\dots\dots\dots\dots\dots\dots \quad (4)$$

Whence:—

$$X_1=X\left\{\frac{100+\Sigma(\alpha)}{100+X\Sigma\left(\frac{\alpha}{A}\right)}\right\} \quad\dots\dots\dots\dots\dots\dots \quad (5)$$

In general the differences between $\Sigma(\alpha)$ and $X\Sigma\left(\frac{\alpha}{A}\right)$ are slight, so that discrepancies due to allowable analytical variations are much less considerable than those mentioned above.

It would therefore appear that experimental results may not be reproduced if the glasses tested be not free from strain or have been insufficiently plained during manufacture. The effect of other ingredients on the moduli of particular oxides is discussed, in the case of MgO, after Table 7. Slight inaccuracies are also possible in the moduli themselves, depending on the operation of the foregoing sources of error upon the glasses examined. Fuller discussion on this point is not at the moment possible, sufficient data being lacking.

It was initially hoped that the wide range of glasses studied by Winkelmann might be employed with advantage in calculating density factors. (Seventy-two glasses in all are described, including silicates, borosilicates, aluminosilicates, borates, phosphates, etc.; *vide* Hovestadt, "Jena Glass," pp. 146—147.) Consideration of the compositions given, however, led to the conclusion that they were not based upon analysis. The fact that the sum of the constituent oxides always lay between 99·9 and 100·1 was taken as at least an indication of recalculation of results to the 100% basis—if not, indeed, calculation from the batch. The absence of traces of impurity normally found even in optical glasses, due to impurities in the raw materials or to solution of the pot substance, appeared to confirm the latter supposition unless all the melts had been made in platinum, a fact which surely would have been recorded. Confirmation of the final conclusion that the results were calculated from the batch was found in a paper by Zschimmer (Z. Elektrochem., 1905, **11**, 629). This finally invalidates Winkelmann's data for the purpose in question, and some of his glasses, selected at random, have shown that even poorer agreement may now be found than with his original moduli,

	Mean square error							0·040	0·023	0·020
	Algebraical sum of errors							0·522	0·005	0·114

the discrepancies being occasionally many times greater than in the case of the analysed glasses discussed below. On all grounds, therefore, Winkelmann's series of factors may be discarded as inherently inadequate to reproduce experimental results with any reasonable degree of accuracy.

Examination of the available data indicated that Tillotson had already discussed the most serviceable observations. Comparison of his tables led to the choice of his 21 melts in the Na_2O—BaO—SiO_2 series from which to derive the factor for combined SiO_2. By selection of three sets of three melts, three slightly different values for SiO_2 were obtained, and from these values for Na_2O and BaO were calculated. The densities of the twenty-one glasses were then computed, using each series of factors in turn, and the results led to the adoption of the following mean values:—SiO_2 2·24; Na_2O 3·20; BaO 7·20. Employing these moduli, Table 2 has been constructed.

It will be clear that, however judged, Winkelmann's factors give the poorest results. There is less difference between the remaining systems and correspondingly closer agreement between calculated and observed results. The slight diminution in the mean square error, however, is regarded as indicating that the factors now proposed are slightly superior.

Larsen's data for CaO—MgO—SiO_2 melts were employed for evaluating the moduli for these bases, the above value for SiO_2 being utilised. As before, several pairs of factors were deduced and applied to the glasses in turn, when the greatest degree of concordance between calculated and observed densities was found to be obtained using the values MgO 4·30; CaO 4·30.

By means of certain of the foregoing values the density of combined Al_2O_3 was deduced from the results of Day and Allen for albite-anorthite mixtures (*loc. cit.*). In agreement with Tillotson, the mean value best representing their results is 2·75. It therefore appears that Winkelmann's value, 4·1, is definitely much too high. The factors have been applied also to English and Turner's CaO—Na_2O—SiO_2 glasses, with results as given.

It will be seen that Winkelmann's factors again fail to reproduce experimental results, and that the factors now proposed show a slight but definite advantage over those published by Tillotson.

Scrutiny of the densities of MgO—Na_2O—SiO_2 glasses recorded by English and Turner (*loc. cit.*) showed that the modulus for combined MgO obtained from Larsen's data was quite unsuitable, since its adoption would necessitate an increase in density on successive replacement of Na_2O by MgO, and not a slight fall as was found experimentally. It was found, however, on consideration of the figures, that the value 3·25 for MgO, in conjunction with the figures previously adopted, expressed the experimental results very closely (Table 7). The compositions and densities of the glasses are shown in Table 6.

* From English and Turner, *loc. cit.*
† Including 0·5% CaO.

Details of minor ingredients are not given in the original. A mean modulus 3·0 has been assigned for use with the factors now proposed, and 3·5 for use with Winkelmann's factors.

The factors tentatively proposed by English and Turner are as follows:—

	Series 1.	Series 2.
SiO_2	2·20 ..	2·30
Na_2O	3·47 ..	2·9
MgO	3·38 ..	2·9

Comparison of Tables 3 and 7 shows that the experimental results are adequately reproduced by the systems of factors proposed, subject to the adoption of the smaller factor for MgO in the latter case. The density of combined MgO therefore appears to exceed that of the free MgO in the $CaO—MgO—SiO_2$ glases and to be less in the $Na_2O—MgO—SiO_2$ glasses. In the former series of melts it is reasonable to suppose that $CaSiO_3$ and $MgSiO_3$ are formed and that the metasilicates are mutually soluble. Indeed, it may simply be demonstrated graphically or by calculation that this assumption meets the facts. On the other hand, it is established from the properties of $Na_2O—MgO—SiO_2$ melts that they could not have resulted simply in mutual solution of silicates of sodium and magnesium, but that further reactions occurred with the formation of more stable compounds possessing in increasing degrees those qualities of chemical durability usually associated with the term "glass" as the magnesia content increased. The conclusion appears to be indicated that, in alkali-containing melts, the density of combined MgO is less than that of the free oxide, thus making it comparable with Al_2O_3 and Sb_2O_4, but that an increase in density occurs in melts of such composition that no chemical action is probable beyond the formation of a simple magnesium silicate. For this reason, therefore, the value 3·25 has been adopted for the density of combined MgO in ordinary glasses, and the results tabulated below have been recalculated

(from the value 4·30 previously adopted) on this basis.

None of the remaining constituents of optical glasses being included in the available published data, the list of moduli was extended from 34 glasses of known composition. Density determinations were made by means of a specific gravity bottle. This was chosen primarily for convenience and immediate availability and the fact that, besides involving neither unusual nor elaborate accessories, it admits of the attainment of a sufficient degree of accuracy without unduly laborious supervision. It is unnecessary in this work to carry results beyond the fourth decimal place to secure accuracy in the third, and the method adopted was found, by the concordance between duplicate determinations, to be sufficiently delicate. This degree of accuracy corresponds to an error rarely exceeding 0·04% and further refinement is needless. Densities were determined on clean, freshly-broken fragments which were brushed free from dust, thus almost wholly eliminating trouble from adherent air-bells. Water was employed throughout, none of the glasses exhibiting sufficient solubility to negative its use. The succeeding tables show the compositions and densities of the glasses employed, and the degree of correlation between the observed values and those calculated by the various systems of factors.

Density factors for PbO and K_2O were calculated to be 10·30 and 3·20 respectively. After making correction for the small amounts of Sb_2O_4, ZnO, and B_2O_3 by means of factors subsequently deduced, the following densities were calculated.

The factor 5·94 was deduced for ZnO from No. 1 of Table 10 and the small corrections for minor con-

stituents have been applied from the factors calculated later.

Employing the factors 2·90 and 3·00 for B_2O_3 and Sb_2O_4 respectively, the following were calculated.

The following table summarises the errors found in applying the various systems of moduli to the glasses discussed.

TABLE 14.

Arithmetical mean of errors	0·058	0·029	0·018
Mean square error	0·071	0·041	0·026
Algebraical sum of errors ..	4·109	0·729	0·118

Summary.

(1) The relation between the density and the composition of glasses has been re-investigated.

(2) The moduli proposed by Winkelmann and Schott have been found to lead to discrepancies exceeding 2% in the case of glasses of normal types. The more satisfactory moduli proposed by Tillotson have been shown to be susceptible of certain improvements.

(3) New moduli are proposed whereby glasses of extreme composition may be included with as high a degree of accuracy as was formerly possible for glasses of normal composition.

(4) Applied to 91 glasses, the new moduli have been found to lead to the smallest average error, the smallest mean-square error, and the lowest algebraical sum of errors.

(5) The theory has been discussed and the reasons for certain discrepancies are indicated.

I wish to acknowledge the assistance of my former colleague, Mr. W. T. Lockett, in the experimental work and the calculations involved. Thanks are due also to Mr. G. H. Perry, O.B.E., Director of Chemical Inspection, for the interest he has shown in this work, and to the Director of Artillery, War Office, for permission to embody in the paper analytical and other results obtained in the work of this laboratory.

THE BACTERIAL PURIFICATION OF TRADE WASTES.

BY DR. G. McGOWAN.

The Ninth Report of the Royal Commission on Sewage Disposal* deals with the disposal of liquid wastes from manufacturing processes. The outbreak of the war, however, cut short the study of the subject, and various points requiring investigation were of necessity left untouched or unfinished. One of these was to acquire accurate experimental data with regard to the amenability of different trade wastes to bacterial purification or, in other words, to ascertain the respective volumes which could be treated on a cubic yard of contact bed or percolating filter. Since that time the activated sludge process of sewage purification has gained increasing prominence, and as this process largely conserves the nitrogen of sewage, it may be expected to become more widely applied as time goes on. Still, the data to be given in the present paper will apply so long as the purification of sewage on contact beds and percolating filters continues; and, besides, the relative rates at which different trade effluents undergo oxidation affect the activated sludge process also.

*Cd.7819 (1915).

The bacterial treatment of domestic sewage is now fairly well systematised, the volume which can be dealt with on unit of filter depending on the strength of the sewage or tank liquor. This "strength" is measured in terms of the oxygen required to oxidise fully the organic matter and ammonia present. 100,000 parts by weight of a sewage of average strength require about 100 parts by weight of oxygen for this purpose.†

To estimate the strength of a sewage or other polluting organic liquor, a small measured volume is mixed with a large measured volume of good tap water, *i.e.*, with excess of dissolved oxygen, and the oxygen in solution is determined (*a*) at the time of mixing and (*b*) after all the oxidisable matter present has been oxidised. The difference between the two figures found gives the amount of oxygen taken up by the sewage or other liquor.

The procedure followed in this determination of dissolved oxygen absorption is to be found in the Eighth Report of the Royal Commission, Vol. II., Appendix, p. 93 *et seq.* [Cd. 6943 (1913)], but a short outline of it may be given here. The requisite dilution having been made with water at a temperature of about 18° C., the liquid is poured quietly, in alternate sections, into two bottles, (*a*) a smaller one of about 350 c.c. capacity, in which the determination of the initial oxygen is immediately made, and (*b*) a quarter-Winchester of 600—700 c.c. capacity, with a well-fitting stopper. Both bottles are of course filled full to overflowing. After the stopper of the quarter-Winchester has been firmly inserted and tied down with tape, a small piece of wide rubber tubing of about 20 mm. internal diameter and 50 mm. long is slipped over it, the top of the rubber remaining about 15 mm. above the head of the stopper. The rubber joint is then nearly filled with mercury and the bottle set aside until the oxidation has completed itself. Unless the glass stopper should have been a bad fit, which rarely happens, this forms a satisfactory joint for the purpose.

At the end of the period allowed for this "long aeration," the small quantity of gas which has collected at the top of the bottle is transferred and analysed, the figure for the oxygen which it contains being added to that for the oxygen in the residual liquid. The method of the transference is described in the Eight Report, Vol. II., Appendix, p. 149. It should, however, be added that bottles which have been jointed for a number of years, like those referred to in this paper, may have the stopper so firmly cemented in that this treatment is at first insufficient to loosen it. In that case, after pouring a drop or two of water on to the stopper, the rubber and mercury (not the tape) should be replaced and another trial at opening made next day. I have in the most persistent cases had to try three or four times in this way before succeeding in getting the stopper loosened. The precautions necessary for the estimation of the residual oxygen in the liquid are detailed in the Eight Report, p. 149; I might add here that, instead of liberating the iodine in the water in the presence of some mercury and immediately pouring off, an alternative method is to siphon the liquid into a smaller bottle, previously filled with carbon dioxide, rejecting the first and last portions.

The various samples of trade effluent dealt with in this paper were typical ones drawn by the Officers of the Commission between 1907 and 1914, together with a few drawn later. They were fully analysed at the time by Messrs. A. C. Carter, F.I.C., A. F. Girvan, B.Sc., A.I.C., and the late W. G. Winterson, B.Sc., these analyses including

† *Cf.* Fifth Report of the Royal Commission on Sewage Disposal, Appendix IV., p. 1 *et seq.*; also p. 52 *et seq.* [Cd. 4282 (1910).].

the determination of dissolved oxygen absorption for the shorter periods up to five days or so, and of the initial oxygen of the "long aerations." The residual oxygen of the latter and of the separated gases have been estimated recently by myself (in 1920). The actual quantities of these gases (reduced to N.T.P.) in 58 estimations were:—

	Extremes.	Average.
Carbon dioxide	0 to 0·07 c.c. ..	0·02 to 0·03 c.c.
Oxygen	0 to 0·65 c.c. ..	0·27 c.c.
Nitrogen	0·46 to 3·15 c.c. ..	1·76 c.c.

As it may be useful, for purposes of future reference, that the general character of the samples examined should be known, the reference is given to the pages of the Ninth and Sixth§ Reports of the Commission where, with a few exceptions, the detailed analyses are to be found. The two samples from the jam factories were examined after the publication of these reports, and are therefore not included in them; nor are some of the malt distillery samples. The general character of the latter can, however, be deduced from the other similar samples. Meantime, it will suffice to give here the figure for dissolved oxygen taken up in five days and that required for complete oxidation.

The ratio of the figure for dissolved oxygen absorption in five days at 18° C. to that for complete oxidation is in the case of domestic sewage something like 1:3. A higher ratio—say, 1:6—means that the oxidation as a whole proceeds more slowly, *i.e.*, that the liquor in question is more difficult of oxidation than sewage. Failing, therefore, a full series of estimations for each sample, giving the figures for dissolved oxygen absorption in 2, 5,......*x* days, the ratio between the figures obtained for five days and for complete oxidation may in the meantime be taken as a guide for getting at the amenability of the trade liquor to bacterial treatment.

The length of time which should be allowed for the "long aeration" of trade effluents, *i.e.*, for their (practically) complete oxidation in the laboratory, is difficult to state precisely. Probably three months at a temperature of about 18° C. would be sufficient in nearly all cases, but it would be safer to allow six months, either at 18° C. or at laboratory temperature.

Cotton dyeing and printing.—In the case of the seven samples examined the ratio of A:B varied from 1:3·4 to 1:4·6, the average being 1:4·1—say, 1:4. A waste liquor or partially purified effluent from cotton dyeing and printing, therefore, which takes up about 25 parts of dissolved oxygen from water in five days at 18° C., may be regarded for purposes of bacterial purification as approximately equivalent to a sewage of strength 100.

It is to be noted here that the two lowest ratios, 1:3·4 and 1:3·6, are given by a crude waste and a tank liquor which contained respectively 11·6 and 6·6 parts of suspended organic solids. The foregoing tentative conclusion, therefore, to look upon such waste giving a five days' figure of 25 as equivalent to sewage with a corresponding figure of 33 receives from this some corroboration.

It has also to be borne in mind that here, as in the case of other types of trade effluent, bacterial oxidation will proceed more rapidly the larger the proportion of domestic sewage there is in the mixture.

Cotton bleaching.—The data here are too meagre for any conclusions to be drawn, but the probabilities are that effluents of this class would not differ materially from cotton dyeing and printing effluents, provided that no large excess of hypochlorite was left in them. Any large excess of the latter would of course retard bacterial oxidation.

Paper mills.—Here, again, the data are very few, but the ratio of the five days' figure to that for complete oxidation may with some degree of probability be taken in the meantime as 1:4·5. This would make a paper mill liquor or effluent with a five days' figure of about 22 equivalent to a sewage with a figure of 33.

Tanning and fellmongering.—The ratio here may also be taken tentatively at 1:4·5.

Jam factories.—With almost no data to go upon, nothing can be said here excepting that such liquors are organically very strong and that they are also slow of oxidation. Possibly the proportion of nitrogen to carbon may be too small for the best rate; in these two samples the combined nitrogen would amount to only about 2 and 3 parts per 100,000, respectively. Pending further results, I think that the ratio A:B might be taken at about 1:10.

Malting and brewing liquors.—Although there are only two results here, they indicate that these liquors are readily oxidisable, the ratio A:B being much the same as that for domestic sewage.

Distillery waste.—The purification of waste distillery liquors is gone into in detail in the Sixth Report of the Commission. The samples cited in the tables were drawn for the purposes of that report in 1908–9 (one in 1907).

Grain distilleries.—Here we have four samples altogether of steep water, spent waste, and spent wash (apart from the paper-filtered samples), and three of them were aerated in duplicate. The four gave a ratio of A:B=1:2·5 to 1:3·5, average 1:3·0. Such liquors, therefore, with a five days' figure of about 33 and a strength of 100 would be equivalent to a sewage of strength 100. The actual strength of the undiluted liquors is of course excessive—in the above samples reaching as high as 50 to 60 times the strength of an average sewage. Considering the very high dilutions (up to 1 in 10,000) that had to be made here, the agreement between the figures for dissolved oxygen absorption by the duplicate samples was fairly good. In the second sample of spent waste, which was examined both before and after filtration through paper, 1 part of the suspended solids present required 1·6 parts of oxygen for oxidation, while 1 part of the soluble solids required 4·0 parts oxygen.

Malt distilleries.—The results (leaving spent lees for the moment out of account) are similar to those given by grain distillery liquors. The ratio A:B in the first seven samples varies from 1:2·3 to 1:4·2, average 1:2·8. As modifying this, however, it must be noted that the figures taken for the five days' dissolved oxygen absorption are not quite the true figures; the true figure would probably be more than that for five-sevenths of seven days, while it might be less than that for five-fourths of four days. On the whole, therefore, the ratio may safely be taken as about 1:3—the same as for domestic sewage. The actual strength of the liquors is great, notably that of the pot ale; the others were less strong than those from the grain distillery. With the exception of the pot ale sample, where the very high dilution of 1 in 15,000 had to be made for the long aeration, the other duplicates showed very fair agreement.

Spent lees.—The volume of spent lees in a malt distillery, as compared with that of the pot ale and steep liquor, is so small, and its organic strength so much less, that it hardly requires detailed consideration here. The results obtained with the two samples tabulated above are, however, interesting as showing the slow rate at which oxidation went on. Mixed with the other distillery liquors, therefore, the spent lees will tend to retard the bacterial oxidation of the whole, though its relatively small volume renders this of little moment. I cannot account for the discrepancy between the two figures obtained for the oxidation of the distillation residue from the first sample (83·5 and 58·5).

Summary.—Excepting in the case of the distillery and, inferentially, the brewery waste liquors, the results given in this paper require to be materially supplemented. Pending, however, detailed figures giving the rate of bacterial oxidation of the various kinds of trade waste, this oxidation being carried to its limit, the following wastes may in the meantime be roughly classified as follows:—

	Dissolved oxygen taken up from water in 5 days at 18° C. Parts per 100,000, by weight. About
"Standard" domestic sewage ...	33
Waste liquor from—	
Grain distilleries	33
Malt distilleries	33
Maltings and breweries	33
Calico printing and dyeing ...	25
Calico bleaching ... (probably)	25
Paper mills	22
Tanneries	22
Jam factories	(?)10

In other words, unit section of bacterial filter will purify one volume of "standard" domestic sewage, or one volume of waste distillery liquor, or 25/33 volume of waste liquor from calico printing and dyeing, and so on, all the liquors being assumed as diluted to the same "strength" as the sewage.

Chemical Laboratory,
30, High Street, Ealing, W. 5.

EXAMINATION OF SOME METHODS OF ASCERTAINING THE PURITY OF SACCHARIN.

BY PHYLLIS VIOLET McKIE.

The saccharin prepared from toluene by the usual methods contains, before purification, small quantities of other sulphonic derivatives of toluene. The most common of these impurities are:—

(1) *p-Sulphamidobenzoic acid.*

(2) *Ortho- and para-toluenesulphonamides.*

(3) *o-Sulphamidobenzoic acid.*—Statements in the literature regarding the isolation of this acid are misleading. It is described by Fahlberg (Ber., 1888, 21, 243) as being very easily soluble in water, and for that reason only isolated by ethereal extraction. I

have, however, prepared this acid, and find that subsequent strong acidification of the mother liquor, which had been three times extracted with ether and gave by this means 61·5% of the theoretical yield of *o*-sulphamidobenzoic acid, deposited crystals of the same acid on standing representing a further 14%. It is therefore possible to "salt out" this acid with strong mineral acid. As saccharin is isolated by a similar "salting out," it is probable that the *o*-sulphamidobenzoic acid will, if present, be precipitated, to a certain extent with the saccharin.

(4) *Toluene-2.4-disulphonamide.*

(5) *Toluene-2.4-disulphonic acid.*

The presence of any of the above substances in commercial saccharin is variously indicated. Three criteria are of value in estimating the purity of saccharin:—

(a) *Depression of the melting point.*—The presence in saccharin of small amounts of impurity causes in several cases considerable depression (10°—15°) of the melting point.

(b) *Incomplete solubility in sodium bicarbonate.*—The presence of certain impurities is also indicated by incomplete solubility in aqueous sodium bicarbonate. Ortho and para-toluenesulphonamide and toluene-2.4-disulphonamide, in that they are extremely weak acids, are insoluble in this reagent. This property, moreover, as well as specifically indicating the presence of one or other of these substances, affords a means of eliminating them from the saccharin mixture.

(c) *Hydrolysis.*—Saccharin is hydrolysed in acid solution to *o*-sulphobenzoic acid and ammonia. Determination of the quantity of ammonia thus evolved from a known weight of commercial saccharin is, under certain conditions, a criterion of its purity.

(a) *Depression of melting point.*

The effect of each of the most common impurities, *p*-sulphamidobenzoic acid, *o*-toluenesulphonamide, and *o*-sulphamidobenzoic acid, on the melting point of saccharin has been examined.

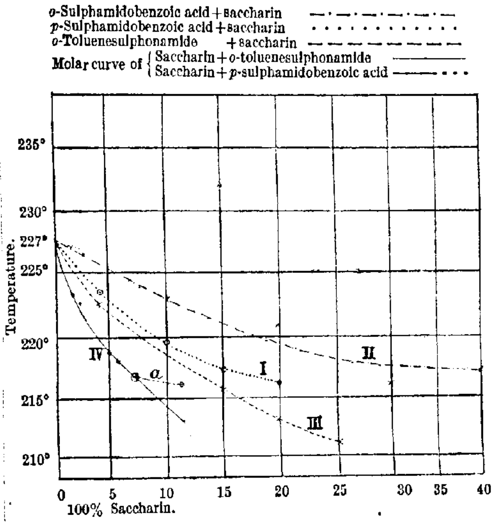
The melting point of saccharin formerly given in the literature is 220° C. with partial decomposition (Mosso, Jahresb., 1887, 2585), but completely pure saccharin melts at 227°—227·5° C. (corr.) and shows no sign of decomposition; it re-solidifies and melts again at the same temperature. Richmond and Hill (J., 1919, 8 T) give m.p. 229° C.

p-Sulphamidobenzoic acid.—Mixtures of pure saccharin and *p*-sulphamidobenzoic acid of varying composition have been examined, and a diagram of the curve of the depression of the melting point of saccharin by successive additions of *p*-sulphamidobenzoic acid is given (*cf.* curve I.).

Melting point of p-sulphamidobenzoic acid.—Palmer (Amer. Chem. J., 4, 164) describes this acid as decomposing at 280° C. without melting, but this statement is erroneous. Even with markedly impure specimens such behaviour was never observed. Perfectly pure *p*-sulphamidobenzoic acid, prepared by repeated recrystallisation from water, has a sharp m.p. of 288°—289° C. (corr.), with no obvious sign of decomposition. On cooling, the substance partially re-solidified and melted again at 250°, showing that some decomposition had in actual fact occurred. This mixture again solidified, and a third melting point, showing marked decomposition, was observed at 300°.

It will be seen from the figure that the melting point is a fairly safe guide as to composition for mixtures containing from 0 to 10% of *p*-sulphamidobenzoic acid, the depression for which is normal, but the melting points of mixtures with a higher content of *p*-sulphamidobenzoic acid than 10% seem to indicate abnormality, as is shown by the marked flattening of the curve in the region of 15% *p*-sulphamidobenzoic acid. Hence, in the case of mixtures of a lower melting point than 219·5° C. (the melting point of a 10% mixture) melting point is not a safe guide as to the content of *p*-sulphamidobenzoic acid.

o-Sulphamidobenzoic acid.—As before, the upper region of the curve of the depression of the melting point of saccharin by *o*-sulphamidobenzoic acid has been examined. The curve appears to be a straight line (curve II.), but in view of the fact that *o*-sulphamidobenzoic acid at a temperature of 180° changes into saccharin and *o*-benzoic ammonium sulphonate (Fahlberg, *loc. cit.*), the melting points of mixtures of this substance and saccharin cannot be taken as trustworthy evidence of the composition.



Melting points of mixtures of saccharin with allied substances.

p-Sulphamidobenzoic acid.			*o*-Toluenesulphonamide.			*o*-Sulphamidobenzoic acid	
%	Mols.*	M.p.	%	Mols.*	m.p.	%	m.p.
10	0·04975	219·5°	5	0·02907	221·5°	10	223·0°
15	0·07463	217·5°	10	0·05815	218·5°	25	221·0°
20	0·09949	216·0°	20	0·11620	213·5°	35	216·5°
						40	214·0°

* On the graph these numbers are shown multiplied by 100.

o-Toluenesulphonamide.—The depression of the melting point of saccharin produced by the presence of *o*-toluenesulphonamide is uniformly normal. Hence the melting point curve (curve III.) of these two substances is parallel to that of *p*-sulphamidobenzoic acid and saccharin up to the point at which the latter becomes abnormal, and since the molecular weights of *p*-sulphamidobenzoic acid (201) and *o*-toluenesulphonamide (171) are not appreciably different, is only separated from it by a difference of melting point of 1°—1·5° C.

The divergence of these two curves produced by the abnormality indicated in the melting point curve of *p*-sulphamidobenzoic acid and saccharin is clearly shown by consideration of the "equimolar" curves for these two pairs of substances (curves

IV.). The weight of each substance taken, divided by their molecular weight, gives the number of mols. which produce a depression corresponding to the observed melting point. Since equimolecular quantities of different substances produce equal lowering of melting point, the two curves should be congruent. But, as will be seen from the figure (IVa) that representing the melting point curve of *p*-sulphamidobenzoic acid and saccharin diverges sharply when 15% of *p*-sulphamidobenzoic acid is reached.

(b) *Solubility in sodium bicarbonate.*

Dilute, 6—8% sodium bicarbonate is added, drop by drop, to the powdered saccharin mixture until effervescence ceases, and solid ceases to be dissolved. After standing for some hours the mixture is filtered. Any toluenesulphonamide initially present in the crude saccharin is thus eliminated in this residual solid. The bicarbonate liquor contains the saccharin, plus any *o*- or *p*-sulphamidobenzoic acid present. Addition of moderately strong acid causes all these substances to be precipitated together. Saccharin comes down more slowly than does *p*-sulphamidobenzoic acid, but no separation by this means is practical.

On the other hand, when the bulk of the impurities has been removed by one of the standard procedures, this method can be conveniently used to obtain completely pure saccharin. The purified saccharin, m.p. not lower than 224° C., is dissolved in an equivalent quantity of aqueous sodium bicarbonate. The solution, filtered if necessary, is diluted with boiling water to twenty parts by volume for every one part of saccharin. The mixture, kept at a temperature of about 80° C., is very slowly precipitated with aqueous 5% hydrochloric acid in 30—50% excess. The addition of hydrochloric acid equivalent to 10 g. of saccharin took, under these conditions, six hours. In this way, and by slow cooling in a hot bath, large lustrous crystals with a sharp melting point of 227°—227·5° C. can be obtained.

(c) *Hydrolysis.*

The hydrolysis of saccharin to *o*-sulphobenzoic acid and ammonia by acids of certain strengths is well known, and a method for the estimation of saccharin is based on this reaction (Emmet Reid, Amer. Chem. J., 1899, 21, 461; Proctor, Chem. Soc. Trans., 1905, 87, 242). The method consists in boiling a known quantity of saccharin (0·3—0·5 g.) with $N/1$ hydrochloric acid (50 c.c.) for $2\frac{1}{2}$ hrs. The ammonia is then estimated by the usual method. Experimental examination of this method showed an error of (1) −0·5%; (2) +0·2%; (3) −0·05%; (4) +0·3%, in four different estimations.

Of the sulphonic derivatives of toluene described above as common impurities of crude saccharin, all contain the group $-NH_2$ and are therefore potentially capable of yielding ammonia on hydrolysis. That the validity of this method of estimation of saccharin might be fully tested, it was essential to ascertain whether the conditions favourable to the hydrolysis of saccharin led also to the elimination of the $-NH_2$ group from these substances.

Proctor (*ibid.*) definitely states that the reliability of the process is not affected by the presence of any of the substances which are likely to occur as impurities in unpurified saccharin. This conclusion he bases on an examination of only *p*-sulphamidobenzoic acid and *o*-toluenesulphonamide, which two substances he shows remain entirely unchanged under the conditions of the estimation. He did not, however, examine the behaviour of the three substances *p*-toluenesulphonamide, *o*-sulphamidobenzoic acid, and toluene-2.4-disulphonamide, all of which are possible impurities of saccharin. Proctor's results for *p*-sulphamidobenzoic acid and *o*-toluenesulphonamide have been confirmed.

p-Toluenesulphonamide.—Treatment of the pure amide with $N/1$ hydrochloric acid for $2\frac{1}{2}$ hrs. led to no hydrolysis. In one case the acid liquor was made alkaline and distilled as in the usual Kjeldahl process; no ammonia was detected. In a second experiment the acid liquor after boiling was allowed to crystallise, when a solid with a melting point corresponding to that of pure *p*-toluenesulphonamide was recovered with no appreciable loss of weight.

Toluene-2.4-disulphonamide.—Again no hydrolysis was detected under the standard conditions. The amide does not crystallise out from the mother liquor on cooling, but extraction with ether gives a quantitative recovery of pure toluene-2.4-disulphonamide.

o-Sulphamidobenzoic acid.—This acid stands alone, in that it is hydrolysed to a very large extent —80%—under the standard conditions.

Of these substances, the most common impurity in unpurified saccharin is *p*-sulphamidobenzoic acid. This, as shown above, is not attacked by $N/1$ hydrochloric acid, and hence the recognised method of estimating saccharin holds, in general, fairly accurately. The presence of *o*- and *p*-toluenesulphonamide, and of toluene-2.4-disulphonamide also in no way affects the validity of the process. But the method is not capable of universal application since in the presence of *o*-sulphaminobenzoic acid (a not very uncommon impurity of saccharin) considerable inaccuracy may be introduced. Moreover, the specific detection of this acid is not easy.

In a modification of Proctor's method for the estimation of saccharin (Richmond and Hill, J., 1918, 246 T) the presence of this acid also invalidates the estimation. But in a later paper (*ibid.*, 1919, 8 T) the authors suggest a means of detecting and estimating this acid in mixtures with saccharin.

The above investigation was undertaken at the suggestion of Professor Orton, to whom I am indebted for direction and criticism.
